Papaverine dissolves without colour in strong sulphuric acid, provided that no rise of temperature takes place; but when strong sulphuric acid is poured upon crystals of the base, the heat produced by the reaction is sufficient to give a faint purple colour to the crystals and the solution. With sulphuric acid containing ferric oxide, the coloration is not so strong as with the pure acid. A recently prepared solution of papaverine in sulphuric acid gives, on addition of water, a milky turbidity or a resinous precipitate which is quickly converted into colourless crystals of papaverine sulphate. No other alkaloid of opium exhibits this reaction; the solution of pseudomorphine in strong sulphuric acid also gives a precipitate with water, but it is crystalline. When a solution of papaverine in strong sulphuric acid is heated, it assumes a dark violet colour, and on subsequent addition of water, deposits dark brown amorphous flocks which are nearly insoluble in dilute sulphuric or hydrochloric acid, also in ether, alcohol, and water, but dissolve readily in strong sulphuric acid, potash, and ammonia, with splendid purple-red colour, and are re-precipitated from the ammoniacal solution by acetic acid. The purple-red basic solution possesses great tinctorial power.

Papaverine hydrochloride, $\text{C}^{21}\text{H}^{21}\text{NO}^4.\text{HCl}$, obtained by saturating the alcoholic solution of the base with hydrochloric acid, forms large prisms having an acid reaction, soluble in 37.3 pts. water at 18° ; when dissolved with aid of heat, it is very apt to form supersaturated solutions.

E. L. Mayer (*Deut. Chem. Ges. Ber.* iv. 128) states that when this salt is treated for a short time with zinc chloride at 125° , it is converted into the salt, $\text{C}^{21}\text{H}^{19}\text{NO}^4.2\text{HCl}$, by elimination of 1 mol. H^2O from 2 mol. of the original salt. According to Hesse, however, this supposed new derivative is nothing but papaverine hydrochloride. By prolonged action of zinc chloride, especially at a high temperature, the molecule is decomposed. **Papaverine platino-chloride**, $2(\text{C}^{21}\text{H}^{21}\text{NO}^4.\text{HCl}).\text{PtCl}_4 + 2\text{H}^2\text{O}$, is a yellow precipitate made up of small prisms. The *nitrate* forms large prisms. The *acid tartrate* is easily soluble. The *acid oxalate*, formed from oxalic acid and the base, crystallises in white prisms, easily soluble in hot alcohol, sparingly in cold alcohol; 1 pt. dissolves in 388 pts. water at 10° . The base is completely precipitated from its solutions by oxalic acid.

Nitropapaverine, $C^{21}H^{28}(NO^2)NO^4$, is prepared by heating 1 pt. of papaverine with about 10 pts. nitric acid of sp. gr. 1.06 to the boiling point, decomposing the nitropapaverine nitrate which separates on cooling, with ammonia, dissolving the separated base in hydrochloric acid, precipitating it as sulphate, separating it from this salt by ammonia, and recrystallising from boiling dilute alcohol. During the recrystallisation and drying it must be kept in the dark, as light colours it yellow.

Nitropapaverine generally forms pale yellow prisms, felted together to a woolly mass; better developed prisms are obtained by crystallisation from strong alcohol. When crystallised from dilute alcohol or precipitated by ammonia, it contains 1 mol. water which is given off at 163° , the melting point of the base, which at the same time acquires a yellow or brown colour. On further heating it quickly gives off gas and detonates. Nitropapaverine dissolves in 3,100 pts. ether at 12° ; sparingly in cold alcohol; with moderate facility in boiling alcohol; sparingly in boiling benzene; easily in chloroform; not at all in water, potash-ley, or ammonia. It is tasteless, and does not redden litmus; its salts have a bitter taste and acid reaction. Acetic acid dissolves the base with difficulty, and only when employed in large excess. Strong sulphuric acid dissolves it in the cold with yellow, at 150° with a dirty dark brown colour.

Nitropapaverine hydrochloride, $C^{21}H^{28}(NO^2)NO^4.HCl + 1\frac{1}{2}H^2O$, forms pale yellow, silky, delicate prisms; dissolves in 288 pts. water at 16° , freely in boiling water and alcohol; easily forms supersaturated solutions. With *mercuric chloride* it forms a yellowish amorphous double salt, insoluble in cold water, moderately soluble in hot water and hot alcohols. The *platinic-chloride*, $2(C^{21}H^{28}(NO^2)NO^4.HCl).PtCl_4$, is a yellow crystalline precipitate, soluble in water and in dilute acids. The *auro-chloride* is a yellow amorphous precipitate, very slightly soluble in boiling water.

The *hydrobromide* forms yellow prisms slightly soluble in water. The *hydriodide*, $C^{21}H^{28}(NO^2)NO^4.HI$, is precipitated by potassium iodide from a hot dilute solution of the hydrochloride, in rectangular laminæ or short prisms having the colour of lead iodide, very slightly soluble in hot water.

The *nitrate*, $C^{21}H^{28}(NO^2)NO^4.NO^3H + H^2O$, is obtained by adding sodium nitrate to the hot dilute solution of the hydrochloride, and recrystallising the precipitate from hot water. It likewise separates instantly on mixing the concentrated solution of the acetate with nitric acid, as a gelatinous precipitate, which is quickly converted into fine prisms. It is sparingly soluble in boiling water, and almost insoluble in cold water.

PARAFFINS, C^xH^{2x+2} . *Boiling points*.—The boiling points of the normal paraffins, that is of those whose carbon-atoms form a single chain, are as follows:—

	Boiling point	Difference
Butane, C^4H^{10}	1°	
Pentane, C^5H^{12}	38	37°
Hexane, C^6H^{14}	70	32
Heptane, C^7H^{16}	99	29
Octane, C^8H^{18}	124	25
Dodecane, $C^{12}H^{26}$	202	4 x 10
Heedecane, $C^{18}H^{38}$	278	4 x 19

From this it appears that the boiling point is not raised 31° for each addition of CH^2 , as formerly assumed, but that from the lower to the higher terms of the series the difference between the boiling points decreases by 4° , till it becomes the well-known difference of 19° (Schorlemmer, *Proc. Roy. Soc.* xvi. 367).

On the Refraction-equivalents of the Paraffins, see LIGHT (p. 740).

Action of Chlorine.—When chlorine is passed into a liquid paraffin, a portion of the monochloride first formed is always further acted on by the chlorine before all the hydrocarbon has been attacked; but the formation of such higher chlorides may be almost completely avoided by bringing the chlorine in contact with the vapour of the boiling hydrocarbon; the monochlorides, being less volatile than the higher chlorides, condense at once, and are thus brought out of the reach of an excess of chlorine.

When any paraffin higher than ethane is thus treated with chlorine, two monochlorinated derivatives are obtained, a primary and a secondary; and these, when heated with potassium acetate and glacial acetic acid, are converted into the corresponding acetates. Neither the chlorides nor the acetates can be satisfactorily separated from one another by fractional distillation, but by heating the mixed acetates with potash, they are transformed into a primary and a secondary alcohol, the separation of which may be very completely effected by fractional distillation (Schorlemmer, *Phil.*

Trans. 1872, p. 111; *Ann. Ch. Pharm.* clxi. 263; *Chem. Soc. J.* x. 1038; xi. 319). See further, **HEXANE**, **HEPTANE**, and **OCTANE**, in this volume.

Formation of Olefines from Paraffins.—Any paraffin whatever, except marsh-gas, is theoretically resolvable into a paraffin of lower order, and one or more olefines, according to the general equation:

For example,

One example of this decomposition has long been known, viz. the resolution of butane C^4H^{10} into ethane C^2H^6 and ethene C^2H^4 , in the action of zinc on ethyl iodide, whereby butane is first formed according to the equation $2C^2H^5I + Zn = ZnI^2 + C^4H^{10}$, and then decomposed in the manner just mentioned (1st *Suppl.* 706); and it has lately been shown by Thorpe & Young (*Ann. Ch. Pharm.* clxv. 1; *Chem. Soc. J.* [2], ix. 342; x. 802) that solid paraffin, exposed to a high temperature in a closed vessel, is almost completely resolved, with evolution of but little gas, into liquid hydrocarbons. This conversion is readily effected on a small scale by sealing up a few grams of solid paraffin into a U-tube of hard glass surrounded by wire-gauze. The limb containing the paraffin is gently heated in a combustion-furnace, and as soon as it has distilled over, the gas is turned down, and the tube when cold is reversed, and the paraffin distilled again; on repeating this process, the paraffin becomes softer and softer, and at last remains liquid. When solid paraffin is heated under the common pressure in a vessel connected with inverted condensers, it is not altered, and further, it appears that only the higher members of the paraffin series undergo this decomposition. Thus a mixture of paraffins and olefines boiling at about 225° was not at all changed by treating it as above described.

To gain further insight into the nature of this decomposition, $3\frac{1}{2}$ kilograms of paraffin from shale, melting at 46° , and composed of 85.14 p.c. carbon and 14.81 hydrogen, were heated in an apparatus consisting of two wrought-iron mercury bottles, connected by a bent iron tube provided with stopcock and valves. One of these bottles was charged with the paraffin and heated over an ordinary coal fire, the heat being so regulated as to produce a pressure of 20 to 25 pounds per square inch in the apparatus; the other bottle served as a condenser to receive the volatilised products. The operation was completed in four or five hours.

The liquefied product thus obtained amounted to 4 litres of liquid hydrocarbons, consisting of a mixture of paraffins and olefines. This mixture was fractionally distilled, the separate fractions were treated with bromine, and the bromides $C^mH^{2m}Br^2$ were separated from the paraffins C^mH^{2m+2} . If the bromides decomposed during distillation, they were converted into the brominated derivatives $C^mH^{2m}Br$ by boiling with alcoholic potash.

	Boiling point	Specific gravity
Pentane, C^5H^{12}	35–37°	
Hexane, C^6H^{14}	67–68	0.6631 at 18°
Heptane, C^7H^{16}	97–99	0.6913 „ 18.6
Octane, C^8H^{18}	122–125	0.7165 „ 15.6
Nonane, C^9H^{20}	147–148	0.7279 „ 13.6

The brominated products obtained were:—

$C^5H^{10}Br^2$	184–188°	
$C^6H^{12}Br^2$	195–200	1.5967 at 20°
$C^7H^{14}Br^2$	Decomposed when heated	1.5146 „ 18.6
$C^8H^{16}Br$	185–190	
$C^9H^{18}Br$	208–212	

The chloride, $C^9H^{18}Cl^2$, boils at about 235° with decomposition.

A paraffin of high boiling point obtained in the distillation of paraffin-oil from Bog-head coal is described by J. Galletly (*Chem. News*, xxiv. 227). It looks like bees-wax, but is crystalline and does not exhibit a conchoidal fracture. It melts at about 80° , boils at a red heat, and is partly resolved by distillation into liquid hydrocarbons.

The solubility of paraffin in benzene is less, and its specific gravity is greater, the higher its melting point, as may be seen from the following table:—

With *acetyl chloride*, sodium-nitromethane might be expected to yield nitro-acetone according to the equation :

but, on adding water after the violent reaction was over, white flakes separated out, probably consisting of a condensation-product (Meyer a. Rilliet).

Sodium-nitromethane, treated with *ethyl chlorocarbonate* in presence of absolute alcohol or ether, forms a brown oily body—not improbably ethyl nitroacetate—which is carbonised by distillation (Meyer a. Rilliet).

Bromonitromethanes.—The monobrominated compound, $\text{CH}^{\text{a}}\text{Br.NO}^{\text{a}}$, is formed by the action of bromine on dry sodium-nitromethane. It is a limpid, heavy, very refractive liquid, boiling at 143° – 144° , very caustic, having a pungent irritating smell and acid reaction.

Dibromonitromethane, $\text{CHBr}^{\text{a}}.\text{NO}^{\text{a}}$, is not easily formed. The best yield was obtained by cooling equivalent quantities of the monobromo-compound and aqueous potash with ice, mixing them rapidly, and pouring the solution into well-cooled bromine; some bromopictin is formed at the same time. Dibromonitromethane is a colourless liquid having a very irritating odour, and boiling with decomposition at 155° – 160° (J. Tscherniak, *Deut. Chem. Ges. Ber.* vii. 916).

Nitroethane, $\text{C}^{\text{a}}\text{H}^{\text{a}}\text{NO}^{\text{a}} = \text{CH}^{\text{a}}.\text{CH}^{\text{a}}\text{NO}^{\text{a}}$, is formed by the action of silver nitrite on ethyl iodide, and is easily obtained pure by distillation and rectification in an oil-bath. Some nitrous ether is always formed at the same time, and about a fifth part of the ethyl iodide escapes decomposition, even when it is heated for a long time in a sealed tube with excess of silver nitrite.

Nitroethane is a colourless, strongly refractive liquid, having an agreeable and peculiar ethereal odour. Sp. gr. = 1.0582. Boiling point, 111° – 113° (ethyl nitrite boils at 16°). The vapour is inflammable and burns with a pale yellow flame, but does not detonate, even when heated considerably above its boiling point. By reduction with iron and acetic acid it is converted into amido-ethane (ethylamine), $\text{C}^{\text{a}}\text{H}^{\text{a}}\text{NH}^{\text{a}}$ (Meyer a. Stüber, *Deut. Chem. Ges. Ber.* v. 399). With acetic anhydride it forms a crystalline solid melting at low temperatures, and apparently consisting of nitro-ethyl-methyl ketone, $\text{C}^{\text{a}}\text{H}^{\text{a}}\text{NO}^{\text{a}}.\text{CO.CH}^{\text{a}}$ (Meyer a. Wurster, *ibid.* 1029).

When nitroethane is dissolved in well-cooled fuming sulphuric acid, and the mixture is gently heated, a very violent reaction sets in, gases being evolved and ethene-disulphonic acid being formed.

A solution of nitroethane in common sulphuric acid undergoes on standing a violent decomposition if the quantity of acid is not large. But by using an excess (about 15 times) and working with small portions, a reaction sets in only when the liquid is boiled carefully for a few minutes. The products consist of acetic acid and a small quantity of another acid, forming an amorphous barium salt. The latter acid is produced in larger quantity by acting on nitroethane with well-cooled fuming acid for several days (Meyer a. Wurster, *ibid.* vi. 1168).

Sodium-nitroethane, $\text{C}^{\text{a}}\text{H}^{\text{a}}\text{Na}(\text{NO}^{\text{a}}) = \text{CHNa}(\text{NO}^{\text{a}}).\text{CH}^{\text{a}}$, is easily formed, either by heating a solution of nitroethane in anhydrous benzene with sodium, or by the addition of an alcoholic soda-solution to nitroethane. In the first case the sodium is converted, with violent evolution of gas, into a white powder which, after washing with ether, is the pure sodium-compound. In the second case the mixture becomes warm and at once solidifies to a white mass, which simply requires to be washed on the filter with absolute alcohol, and to be dried in the water-bath. The second method of preparation also affords a ready method of detecting nitroethane; owing to the slight solubility of the sodium-derivative in cold alcohol, even traces of nitroethane yield a precipitate on the addition of an alcoholic soda-solution. Neither alcoholic potash nor alcoholic ammonia produces a precipitate with nitroethane.

Sodium nitroethane is a white, apparently amorphous powder, which explodes only at temperatures above 100° ; it is extremely soluble in water, acids precipitating unchanged nitroethane from the solution. The aqueous solution is not precipitated on the addition of barium chloride or lead acetate; mercurous nitrate causes a grey, silver nitrate, a white precipitate, the latter rapidly becoming brown and finally black; copper sulphate produces a deep green, ferric chloride a blood-red solution. On the addition of mercuric chloride, the solution solidifies, after a short time, to a mass of crystalline needles which have the composition $\text{HgCl}^{\text{a}}\text{C}^{\text{a}}\text{H}^{\text{a}}\text{NO}^{\text{a}}$, and may be regarded either as $\text{Hg} \begin{Bmatrix} \text{Cl} \\ \text{C}^{\text{a}}\text{H}^{\text{a}}\text{NO}^{\text{a}} \end{Bmatrix}$, or as $\text{Hg} \begin{Bmatrix} \text{C}^{\text{a}}\text{H}^{\text{a}}\text{NO}^{\text{a}} \\ \text{C}^{\text{a}}\text{H}^{\text{a}}\text{NO}^{\text{a}} \end{Bmatrix} + \text{HgCl}^{\text{a}}$ (Meyer a. Stüber, v. 514).

When an aqueous solution of sodium-nitroethane, or a solution of nitroethane in caustic potash or soda, is mixed with potassium nitrite and acidulated with sulphuric acid, no nitroethane is precipitated; but on agitating with ether, and leaving the

etheral solution to evaporate, splendid crystals are obtained, grouped in druses like prohnite. These crystals consist of ethyl-nitrolic acid, $C^2H^3NO^3$, or $CH^3.CO.NH.NO^2$, and their formation may be represented by the equation:

The same compound is obtained by dissolving nitroethane in alcoholic potash, adding sulphuric acid, agitating with ether, and evaporating. In this case, part of the nitroethane appears to give up NO^2 to the potash, forming potassium nitrite, which then acts on the remaining nitroethane as above.

Ethyl-nitrolic acid melts at $80^\circ-81^\circ$, and quickly decomposes, giving off nitrogen and its tetroxide, and leaving glacial acetic acid:

The ethyl-nitrolates of potassium, sodium, ammonium, and bromine dissolve in water with deep red colour; those of the heavy metals are coloured very unstable precipitates, easily changing into nitrites. The lead salt has a brilliant orange colour, the silver salt is egg-yellow (V. Meyer, *Deut. Chem. Ges. Ber.* vii. 425).

Ethyl-nitrolic acid is the representative of a class of acids called nitrolic acids, having the general formula, $C^xH^{2x}N^2O^3$.

Methyl-nitrolic acid, $CH^3N^2O^3$, is obtained from nitromethane, by a reaction similar to the above, in small granular crystals (Meyer, *ibid.* vi. 1492).

Bromonitroethanes (Meyer a. Wurster, *ibid.* vi. 94; J. Tschorniak, *ibid.* vii. 916).—By adding bromine to sodium-nitroethane, a heavy oil is obtained, boiling at $152^\circ-157^\circ$, and consisting of a mixture of nitroethane with its mono- and dibrominated derivatives.

Monobromonitroethane, $CH^3-CHBr(NO^2)$, can be obtained nearly pure by a long-continued fractional distillation. It is a very heavy oil, smelling like chloropierin, and boiling at $145^\circ-148^\circ$ (Meyer a. Wurster), $155^\circ-160^\circ$ (Tschorniak). It dissolves in strong aqueous potash or ammonia, with evolution of heat, and yields crystalline compounds with a concentrated soda-solution and alcoholic ammonia. These salts, however, always contain some metallic bromide, and for this reason it is impossible to purify the crude monobromonitroethane by dissolving it in alkalis and precipitating it with acids, the product thus formed having a less constant boiling point than the original substance, and leaving on distillation a residue, which decomposes with deflagration and formation of a dense black smoke.

Dibromonitroethane, $CH^3-CBr^2(NO^2)$, has no acid properties, and can easily be obtained pure by treating the higher-boiling fraction with potash. It is a limpid, mobile liquid, having the same pungent smell as the monobromo-compound, and boiling at $162^\circ-164^\circ$ (Meyer a. Wurster), $155^\circ-160^\circ$ (Tschorniak).

The different degrees of acidity of nitroethane and its two brominated derivatives are easily explained by their constitution, as represented by the following formulæ—

Nitroethane and its monobromo-derivative contain hydrogen and nitril in association with the same carbon-atom, the hydrogen being therefore rendered replaceable by metals, in consequence of its proximity to the negative nitril; both are therefore acid, but in the second the acid character is enhanced by the introduction of another negative radicle, viz. the bromine. In dibromonitroethane, on the other hand, both the basylous hydrogen-atoms of nitroethane are replaced by bromine, and therefore the compound is neutral (Meyer a. Tschorniak, *Deut. Chem. Ges. Ber.* vii. 712).

Nitropropanes, $C^3H^5NO^2$. *Normal Nitropropane*, $CH^3-CH^2-CH^2NO^2$, is produced, together with propyl nitrite, by the action of propyl iodide on silver nitrite mixed with an equal volume of sand. It is a limpid mobile liquid very little heavier than water, and boiling at $122^\circ-127^\circ$. Its properties are similar to those of nitroethane. Its sodium salt gives characteristic precipitates with salts of the heavy metals (p. 896) (Meyer a. Rilliet, *Deut. Chem. Ges. Ber.* v. 1029). On dissolving it in aqueous potash, adding potassium nitrite and sulphuric acid, agitating with ether, and evaporating, propyl-nitrolic acid, $C^3H^5N^2O^3$, or probably $CH^3.CH^2.CO.NO^2.NH$, is obtained in long silky needles (Meyer a. Locher, *ibid.* vii. 670).

Isonitropropane, $CH^3-CH(NO^2)-CH^3$, is obtained, together with isopropyl nitrite, in a similar way as the other nitro-compounds. It boils at $112^\circ-117^\circ$. Its sodium-compound is deliquescent, and more soluble than that of normal nitropropane.

When potassium nitrite and sulphuric acid are added to an alkaline solution of isonitropropane, a deep blue liquid is obtained, which soon deposits a white sandy crystalline powder, isomeric with propyl-nitrolic acid, but not possessing acid properties.

It is called *propyl-pseudonitrol*, and has probably the constitution $\text{CH}^3\text{C}(\text{NO})(\text{NO}^2)\text{CH}^3$. It is insoluble in water, acids, and alkalis, almost insoluble in cold ether, more freely soluble in cold alcohol and chloroform, readily in the hot liquids. Its solutions have a pure blue colour, and it separates on evaporation in white glistening rhombohedrons resembling calcite. When heated it melts with partial decomposition, forming a deep blue liquid (Meyer a. Locher, *ibid.* vii. 670).

The heavy metals give, with the sodium-compounds of nitromethane, nitroethane, and the two nitropropanes, such characteristic precipitates that these reactions may be used for distinguishing these nitro-compounds, as the following table shows. Nitropentane does not form metallic compounds.

Reactions of Nitroparaffins with Metallic Salts (Meyer a. Chojanacki, *Deut. Chem. Ges. Ber.* v. 1034).

	Mercuric chloride	Mercurous nitrate	Ferric chloride
Sodium nitromethane	Light yellow precipitate; explosivo	Black flocculent precipitate	Dark brownish-red precipitate
Sodium nitroethane	White crystalline precipitate	Dirty-grey precipitate	Blood-red coloration
Sodium nitropropane (normal)	White crystalline precipitate	Black flocculent precipitate	Blood-red solution
Sodium nitropropane (iso)	White crystalline precipitate	Black flocculent precipitate	Blood-red solution

	Barium chloride	Copper sulphate	Lead acetate	Silver nitrate
Sodium nitromethane	0	Grass-green precipitate	White precipitate	White precipitate, turning almost immediately black
Sodium nitroethane	0	Deep green solution	0	White precipitate, soon turning brown
Sodium nitropropane (normal)	0	Deep green solution	White precipitate	White precipitate, gradually turning brown
Sodium nitropropane (iso)	0	Deep green solution	0	Light yellow precipitate, soon turning black

Bromonitropropanes.—Nitroethane, as already explained (p. 895), yields a monobromo-derivative which is more strongly acid than itself, and a dibromo-derivative which is neutral. If other nitro-paraffins behave in the same manner, those which contain a primary alcohol-radicle will also yield an acid monobrominated and a neutral dibrominated derivative, while those containing secondary radicles will yield only a neutral monobrominated derivative, thus—

The correctness of this view is shown by the following facts:—On gradually adding 1 mol. of bromine to a solution of 1 mol. of isonitropropane in 1 mol. of strong potash, pure monobromisonitropropane, $\text{CH}^3\text{OBr}(\text{NO}^2)\text{CH}^3$, separates out as a

heavy, strongly refracting oil, boiling, after one rectification, at 148° – 150° , and having a pungent smell. It is perfectly insoluble in strong potash.

When normal nitropropane is treated in the same way, a mixture is obtained, from which the neutral dibromo-compound can easily be isolated by treating the highest-boiling fraction with strong potash. It is an oily liquid, having a pungent smell, and boiling at 184° – 186° . It is quite insoluble in alkalis. The monobromo-compound can only be purified by continued fractional distillation; it is a similar liquid, boiling for the most part at 155° – 160° . It dissolves in potash with evolution of heat, and is separated again by acids (Meyer a. Tscherniak, *Deut. Chem. Ges. Ber.* vii. 712; see further Tscherniak, *ibid.* 916).

Nitro-isobutane, $C^4H^9(NO^2) = CH(CH^3)^2 - CH^2(NO^2)$. This body was obtained, together with isobutyl nitrite, by acting with isobutyl iodide on a mixture of silver nitrite and sand. It is a pale-yellow light oil, smelling like peppermint, and boiling at 137° – 140° . It is soluble in potash and reprecipitated by acids, but does not give a crystalline compound with alcoholic soda. By iron and acetic acid it is reduced to isobutylamine. It reacts energetically with sulphuric acid, forming isobutyric acid. On dissolving it in an equivalent quantity of potash, and adding bromine, a liquid separates which appears to consist of unaltered nitrobutane, monobromonitrobutane, and dibromonitrobutane. This latter is a pungent oil boiling at 180° – 185° (E. Demoll, *ibid.* vii. 709, 790).

Nitropentane, $C^5H^{11}NO^2$, is formed by the action of silver nitrite on amyl iodide, the action being completed by the heat of an oil-bath. By fractional distillation of the product, portions were obtained boiling at 148° – 153° , 152° – 156° , and 156° – 160° , the greater part passing between 150° and 160° (ordinary amyl nitrite boils at 95°). Nitropentane is strongly acted on by iron and acetic acid, the product giving off an ammoniacal odour on addition of potash. Heated with aqueous potash to 100° in sealed tubes, it gives a product from which sulphuric acid precipitates a heavy oil, not more than $\frac{1}{3}$ of which distils between 80° and 100° , and a small quantity above 160° (Meyer a. Stüber, *ibid.* v. 203).

PARALDEHYDE. See ALDEHYDE (p. 33).

PARA-OXYBENZOIC ACID. This modification of the acid $C^6H^4O^2$ is formed, together with oxybenzoic acid, by the action of melting potash on potassium sulphobenzoate. Slight variations in the mode of preparing the sulphobenzoic acid appear to influence the proportions of the two oxy-acids obtained from it; the largest amount of para-oxybenzoic acid was obtained from sulphobenzoic acid, prepared by exposing benzoic acid to the vapour of sulphuric anhydride, treating the agglomerated mass with fuming sulphuric acid, and gently warming for a short time.

The two oxy-acids cannot be separated by fractional crystallisation, but a partial separation may be effected by adding barium hydrate to the solution of the barium salts of the two acids, whereby basic barium para-oxybenzoate is precipitated without any oxybenzoate, part of the basic para-salt, however, remaining dissolved (Ira Remson, *Zeitschr. f. Chem.* [2]. vii. 81).

Para-oxybenzoic acid is also formed, together with anol or allyl-phenol (1st Suppl. 175), by fusing anethol with potash (Ladenburg, *Ann. Ch. Pharm., Suppl.* viii. 87).

PARASORNIC ACID. See SORNIC ACID.

PARATHIONIC ACID. This name was given by Gerhardt to a supposed isomerido of ethyl-sulphuric acid, the barium salt of which was said to be obtained by boiling the solution of the ethyl sulphate (iv. 354). It has been shown, however, by Kelenmeyer (*Ann. Ch. Pharm.* clxii. 373) and by Scheibler (*Deut. Chem. Ges. Ber.* v. 446), that this supposed isomerido has no existence, the two barium salts being perfectly identical.

PARISIN. This alkaloid, obtained from a cinchona bark, has been shown by Flückiger to be identical with beberine (1st Suppl. 255).

PARVOLINE, $C^8H^{11}N$. This alkaloid has been shown by Vohl a. Eulenberg to be one of the constituents of tobacco-smoke (see TOBACCO).

PATTINE, $C^{11}H^{21}NO + H^2O$. An alkaloid obtained from a white cinchona bark from Payta in Peru (see CINCHONA-BASES, p. 347).

PELARGONIC, or NONYLIC ACIDS, $C^9H^{19}O^2 = C^8H^{17}.COOH$. 1. Pelargonic acid, prepared by the oxidising action of chromic acid mixture on methyl-nonyl ketone, $C^{10}H^{20}O$, from rue-oil (p. 808), and purified by conversion into sodium salt, separation by sulphuric acid, and rectification, forms a light oil which boils at 248° – 250° , solidifies completely at 0° , and melts again at $+7^{\circ}$. Its barium and calcium salts, prepared 2nd Sup.

by precipitating the ammonium salt with the corresponding chlorides, and purified by recrystallisation from hot water, form colourless leaflets unctuous to the touch. The *barium salt* is anhydrous. The *copper salt* is a light green precipitate insoluble even in boiling water, caking together to a resinous mass when heated in the liquid from which it is precipitated, melting in the dry state at 258° ; it dissolves in alcohol with deep green colour. The *silver salt* is a white precipitate nearly insoluble in boiling water (Giesecke, *Zeitschr. f. Chem.* [2], vi. 429).

2. The normal acid, $\text{CH}_2^{\text{C}^{\text{H}^{\text{I}}}}(\text{CH}_2)^n\text{COOH}$, called especially *nonylic acid*, is prepared from the normal octyl alcohol, $\text{CH}_2^{\text{C}^{\text{H}^{\text{I}}}}(\text{CH}_2)^n\text{CH}_2\text{OH}$, of Heracleum-oil, by converting this alcohol into octyl iodide, the latter into cyanide, heating the cyanide with alcoholic potash, and distilling the resulting potassium salt with sulphuric acid. The acid thus obtained is a colourless oily liquid having a faint odour, solidifying to a crystalline mass at low temperatures, and beginning to melt at $+10^{\circ}$; the acid separated from the recrystallised silver salt melts at 12° – 12.5° , solidifies at 11.5° , and gives the same results after distillation, solidification, and strong pressure. It boils at 253° – 254° under a pressure of 758.8 mm., and has a specific gravity of 0.9065 at 17.5° . It dissolves sparingly in water and distils slowly with aqueous vapour.

The *potassium, sodium, and ammonium salts* form small pearly scales; the first is decomposed by hot alcohol, the third on warming its aqueous solution. The *barium, calcium, copper, zinc, and lead salts* separate in crystals from their aqueous solutions; the lead salt appears to be basic. The *methylic ether*, $\text{C}^{\text{H}^{\text{I}}}(\text{CH}_2)^n\text{O}^2$, is a colourless liquid of sp. gr. 0.8765 at 17.5° and boiling at 213° – 214° . The *ethylic ether*, $\text{C}^{\text{H}^{\text{I}}}(\text{C}^{\text{H}})_2\text{O}^2$, has a specific gravity of 0.8655 at 17.5° , and boils at 227° – 228° (Franchimont a. Zincke, *Deut. Chem. Ges. Ber.* v. 19).

3. *Isononylic acid*, $\text{CH}_2^{\text{C}^{\text{H}^{\text{I}}}}\text{CH}^{\text{C}^{\text{H}^{\text{I}}}}\text{COOH}$ (Kuhlthom, *Ann. Ch. Pharm.* cxxxii. 319). This modification is obtained from methyl-hexyl carbinol (castor-oil alcohol) by converting the alcohol into the corresponding cyanide, $\text{C}^{\text{H}^{\text{I}}}\text{CN}$ (isononyl nitril), and digesting this compound with alcoholic potash, whereby it is first converted, by assumption of H_2O , into isononylamide, $\text{C}^{\text{H}^{\text{I}}}\text{CO.NH}^2$, and afterwards into potassium isononylate:

which, when distilled with sulphuric acid, yields isononylic acid.

This acid is a colourless oil, almost insoluble in water, easily soluble in alcohol and ether. Sp. gr. = 0.90325 at 18° . Boils at 244° – 246° . The *sodium salt* is a crystalline mass easily soluble in water and in alcohol; the *potassium salt* forms an amorphous soap. Both these salts may be salted out of their aqueous solution by addition of common salt. The *ammonium salt* is an oil insoluble in water, but soluble in alcohol. The *calcium salt*, $\text{Ca}(\text{C}^{\text{H}^{\text{I}}}\text{O}^2)^2 + \text{H}_2\text{O}$, separates from hot water in masses of needles. The *copper salt* is a green precipitate, or a doughy mass which slowly becomes crystalline. The *silver salt* is a white precipitate which decomposes when heated to 100° or boiled with water. The *ethylic ether* is a colourless oil boiling at 213° – 215° and having a specific gravity of 0.86406 at 17° .

Isononylamide, $\text{C}^{\text{H}^{\text{I}}}\text{CONH}^2$, forms small needles or scales which volatilise with water-vapour, melt at 80° – 81° , and dissolve sparingly in cold water, readily in alcohol and ether. Its aqueous solution heated with mercuric oxide and allowed to cool, deposits mercuric isonylamide in tufts of needles melting at 117° – 118° (Kuhlthom).

Pelargonic acid from oil of rue agrees in boiling point with isononylic acid much more nearly than with Franchimont a. Zincke's *nonylic acid*, from which it also differs considerably in its melting and solidifying points, and in the boiling point of its ethylic ether. It is therefore most probably identical with isononylic acid, whence it must be inferred that oil of rue contains isononylic aldehyde, $\text{CH}_2^{\text{C}^{\text{H}^{\text{I}}}}\text{CHO}$.

PENTACHLORETHANE, $\text{C}^{\text{H}}\text{Cl}_5$. This compound treated with alcoholic potash yields potassium chloride, and a potassium salt which crystallises in needles and probably has the composition $\text{C}^{\text{H}}\text{Cl}_5\text{COK}$ (Hoch a. Kolbe, *J. pr. Chem.* [2], iv. 60).

On the action of bromine on pentachlorethane, whereby the compound $\text{C}^{\text{H}}\text{Cl}_4\text{Br}$ is produced, see CARBON CHLORIDES (p. 258).

PENTACHLOROMETHYL OXIDE, $\text{C}^{\text{H}}\text{Cl}_5\text{O}$. See ETHYL OXIDE (p. 484).

PENTANE, C^{H}_5 . See AMYL HYDRIDE (p. 63).

PERCHLOROMETHYL-MERCAPTAN, CCl_5S . See CARBON SULPHO-CHLORIDES (p. 266).

PERCYLITE, $\text{Pb}^2\text{Cl}^2\text{O} \cdot \text{Cu}^2\text{Cl}^2\text{O} \cdot \text{H}^2\text{O}$. This mineral, originally found at Sonora in Mexico, where it occurs crystallised in cubes (iv. 377), has also been found in South Africa, sometimes in very minute but confused crystals, but generally massive, or as a coating, or in veins, associated with anglesite, cerussite, and chlorargyrite. In this, as well as in the Mexican specimens, the blue colour changes to emerald-green on heating, and reappears on cooling (Maskelyne & Flight, *Chem. Soc. J.* [2], x. 1051).

PRIDOTE. Crystals of this mineral are formed, together with crystals of pyroxene, by heating its constituents, silica, alumina, and magnesia, with calcium chloride (Lechartier, *Compt. rend.* lxxv. 487; *Chem. Soc. J.* [2], xi. 40).

PERIODIDES. See IODINES (p. 677).

PROWSEITE, $\text{CaO} \cdot \text{TiO}^2$. This mineral, though belonging to the regular system, has been found by Hesseberg (*Jahrb. f. Mineralogie*, 1871, 640) to be doubly refractive and optically uniaxial. As, however, a revision of the angular measurements left no doubt of the monometric character of the crystals, and as this result has been confirmed by G. vom Rath (*Pogg. Ann.* cxliv. 595), the double refraction must be attributed to an internal transformation of the substance.

PEROXIDES. *Preparation by Electrolysis*.—W. Wernicke (*Pogg. Ann.* cxli. 109) has prepared several peroxides by subjecting metallic solutions to the action of a two-cell Daniell's battery, the positive electrode being a plate of platinum, and the negative consisting of two sheets of platinum, placed one on each side of the positive electrode.

Lead.—An alkaline solution of lead and sodium tartrate gave a brilliant, bluish-black deposit of $\text{PbO}^2 \cdot \text{H}^2\text{O}$, sp. gr. 6.267. A solution of 1 pt. lead nitrate in 8 pts. water gave, by 36 hours' treatment, anhydrous PbO^2 , sp. gr. 9.045. By treatment for a shorter time, or by using more dilute solutions, products are obtained containing variable quantities of water. It appears that the acid set free at the positive electrode abstracts water from the peroxide, for anhydrous lead peroxide placed in connection with the positive electrode in water containing a little soda, passed into $\text{PbO}^2 \cdot \text{H}^2\text{O}$. The quantity of oxygen in the oxide varies inversely as the strength of the current, for by using six elements of Bunsen's battery, pure hydrated lead oxide was formed.

Manganese.—The preparation of manganese peroxide requires a weaker current. The acetate and nitrate gave $\text{MnO}^2 \cdot \text{H}^2\text{O}$, sp. gr. 2.564.

Bismuth.—Two elements of Daniell's battery gave, with a solution of basic bismuth nitrate in sodium tartrate, a black deposit of $\text{BiO}^2 \cdot \text{H}^2\text{O}$, sp. gr. 5.571.

Cobalt.—An aqueous solution of cream of tartar and hydrated cobalt oxide with a little soda gave $\text{CoO}^2 \cdot 2\text{H}^2\text{O}$, sp. gr. 2.483.

Nickel.—A solution of nickel analogous to that last mentioned gave $\text{NiO}^2 \cdot 2\text{H}^2\text{O}$, sp. gr. 2.744.

PERSEA. The rind, kernel, and fresh pulp of the Avocado pear (*Persea gratissima*), which is eaten in Mexico as a cream with lime-juice, wine, and sugar, have been analysed by L. Glutz (*Arch. Pharm.* [2], cxlvi. 114; *Chem. Soc. J.* [2], ix. 727); 100 pts. of the dried pulp contain 5.109 pts. of ash and 1.353 nitrogen.

PERSULPHIDE OF HYDROGEN, H^2S^2 . See SULPHIDES.

PERSULPHOCYANIC ACID, $\text{C}^2\text{N}^2\text{H}^2\text{S}^2$ (iv. 378). This compound, treated in aqueous solution with phosphorus iodide (i.e. with nascent hydriodic acid), yields— together with carbon sulphide and hydrogen sulphide—the hydriodic acid of sulphurea, which crystallises from hot water in waxy tabular plates:

The hydrogen sulphide is doubtless a product of the action of the hydrogen iodide on the carbon sulphide.

Persulphocyanic acid, treated with tin and hydrochloric acid, dissolves, with evolution of hydrogen sulphide and carbon sulphide, and forms the stannochloride of sulphurea.

Aniline, with the aid of heat, dissolves about half its weight of persulphocyanic acid, and solidifies to a grey mass, which crystallises from boiling alcohol in nacreous scales having the composition $\text{C}^2\text{H}^2\text{S}^2\text{N}^2$:

This compound—which may be regarded as a biuret having its oxygen replaced by sulphur, and 1H by C^2H^2 —is insoluble in water, whether hot or cold, and possesses both acid and basic properties. From solution in soda or ammonia it is precipitated by hydrochloric acid. Its hydrochloride, obtained by dissolving it in dilute aqueous

ferric chloride, dissolves easily in warm water, and crystallises in needles. With *platinic chloride* it forms a double salt which crystallises in needles; with *stannic chloride* and *mercuric chloride* white precipitates. The *oxalate*, *nitrate*, and *sulphocyanate* are sparingly soluble; the *sulphate* is easily soluble (L. Glutz, *Ann. Ch. Pharm.* cliv. 39, 44, 48).

According to A. Fleischer (*Deut. Chem. Ges. Ber.* iv. 100), an alcoholic solution of persulphocyanic acid forms with silver nitrate a yellow precipitate, with mercuric chloride a white precipitate. On boiling it with mercuric oxide, the solution on cooling deposits a beautifully crystallised mercury salt. With iodine very fine crystals are obtained, having a peculiar golden-yellow lustre.

PERTHIOSULPHANHYDRIDE. See PERSULPHIDE OF HYDROGEN, under SULPHIDES.

PETALITE. The crystals of petalite from Elba have been described by G. vom Rath and G. Strüver (*Jahrb. f. Mineralogie*, 1870, 690). The axial ratio $a : b : c = 1.15342 : 1 : 0.743686$; angle $ac = 122^{\circ} 26'$; whence $\infty P : \infty P = 86^{\circ} 20'$.

PETROLEUM. On the Physical Properties and Heating Power of different Petroleum from Russia, see H. Sainte-Claire Deville (*Compt. rend.* lxxii. 191; *Chem. Soc. J.* [2], ix. 453).

On the Hydrocarbons from the Petroleum of Pechelbronn, see J. Le Bel (*Compt. rend.* lxxiii. 499, lxxv. 267; *Chem. Soc. J.* [2], ix. 1025, x. 886).

On Petroleum Exploration in Galicia and America, see A. Fauck (*Dingl. pol. J.* cxi. 158).

PHENACITE. *Glucinum silicate* (iv. 387).—This mineral quickly loses its colour by keeping. A dark wine-yellow crystal was observed by Kokscharow (*Jahrb. f. Mineralogie*, 1870, 103) to become perfectly colourless in two months.

PHENACONIC ACID. This name was given by Carius to an acid isomeric with acetic acid, obtained by the action of baryta-water on trichlorophenomalic acid (1st *Suppl.* 904). Subsequent researches have shown that it is identical with fumaric acid, $C^4H^2O^4$ (*Deut. Chem. Ges. Ber.* iv. 928; *Chem. Soc. J.* [2], x. 144).

PHENANTHRENE. A hydrocarbon isomeric with anthracene (p. 84).

PHENOL. $C^6H^5O = C^6H^4.OH$. *Phenyl alcohol*.—1. A small quantity of this compound is formed, together with glycerin-ether and other products, when glycerin is distilled with calcium chloride (Linnemann a. v. Zotta, *Ann. Ch. Pharm., Suppl.* viii. 254); 14.8 kilograms of glycerin thus treated yielding 250 grains of glycerin-ether, $(C^6H^5)^2O^2$, and 18 grains of pure phenol (v. Zotta, *ibid.* clxxiv. 87). It appears, also, to be produced when glycerin is heated with zinc chloride or hydrogen-potassium sulphate, and by the action of a concentrated solution of potassium hydrate on glycerin-ether.

2. Dumas and Bardsy (*Compt. rend.* lxxiv. 1052) assert that monochlorobenzene, C^6H^5Cl , is converted by heating with aqueous sodium hydrate at 300° into phenol.

3. According to Lieben (*Ann. Ch. Pharm., Suppl.* vii. 240), the first fraction of the distillate from horse's urine contains phenol. It may be separated from the iodoform-yielding substance always furnished by urine, by distillation with a little potassium hydrate, and obtained from the residue by distilling with sulphuric acid. Hoppe-Seyler (*Chem. Soc. J.* [2], x. 628, from *Pflüger's Archiv. f. Physiologie*, v. 470) confirms this statement, and also the earlier observations of Stædeler and Buligin, that phenol can be obtained from urine by distilling it with sulphuric acid; he contends, however, that phenol is not originally contained in urine, but is formed by the action of the sulphuric acid, probably from indican. Similarly, Landolt's observation that bromine-water precipitates directly from urine tribromophenol, or at any rate a substance which yields phenol when treated with sodium-amalgam, does not prove the pre-existence of phenol, because other substances, such as the oxybenzoic acids, yield with bromine-water either tribromophenol or bodies which, on reduction, furnish phenol.

Reactions.—1. Landolt recommends bromine-water as the most delicate test for small quantities of phenol (*Deut. Chem. Ges. Ber.* iv. 770). When added in excess to dilute neutral or faintly acid solution of phenol, this reagent produces an immediate

bulky yellowish precipitate of tribromophenol. In order to ascertain whether the precipitate is tribromophenol, it is filtered off, and after washing is warmed gently in a test-tube with sodium-amalgam and water; the liquid is then poured into a small dish and acidulated, when, if phenol be present, the characteristic odour is at once perceived, and oily drops are seen floating in the liquid. By this reaction 1 part of phenol in 43,700 of water may easily be detected. Para-oxybenzoic acid, however, also yields tribromophenol, and salicylic acid is converted into dibromosalicylic acid, which furnishes phenol with sodium-amalgam and water; other members of the phenol group also furnish similar precipitates with bromine-water.

2. Phenol solutions, boiled with a solution of *mercurous nitrate*, assume a deep red colour, the production of which is due to the presence of a trace of nitrous acid; much more than a trace of this acid renders the colour indistinct. The reaction is very distinct with $\frac{1}{60,000}$ th of phenol, and is still apparent when only $\frac{1}{200,000}$ th is present. Salicyl and salicylic acid behave like phenol (Plugge, *Zeitschr. anal. Chem.* xi. 173).

3. A solution of phenol when mixed with one-fourth its volume of ammonia and a few drops of bleaching-powder solution (1 to 20 of water), and then warmed but not boiled, assumes a blue colour (green in very dilute liquids), becoming red on addition of sulphuric or hydrochloric acid. Solutions containing $\frac{1}{4,000}$ th of phenol give a strong blue reaction (Salkowski, *Zeitschr. anal. Chem.* xi. 316).

4. The behaviour of sodium- and potassium-phenol with *carbonic anhydride* has been studied by Kolbe (*J. pr. Chem.* [2], x. 89). The action of carbonic anhydride on dry sodium phenol commences at a temperature below 100°, but is most rapid and complete at about 170°–180°; on raising the temperature gradually to 220°–250°, phenol distils over equivalent in amount to one-half the sodium-phenol. The operation is ended when phenol ceases to come over; the residue then consists entirely of disodium salicylate. The reaction appears to consist in the formation of 1 mol. of phenol and 1 mol. of disodium-phenol from 2 mol. of sodium-phenol:

the latter of which combines, at the moment of formation, with carbonic anhydride to form disodium salicylate:

When potassium-phenol is similarly treated, the product varies according to the temperature at which the action takes place. At a temperature not exceeding about 145° salicylate only appears to be formed, but if the action take place at 170°–210°, about half the phenol employed as potassium-phenol distils over; scarcely any salicylate is formed however, but the product consists almost entirely of the isomeric para-oxybenzoate.

5. When phenol is fused with an excess of *potassium hydrate* until the mass assumes the consistence of a thick syrup, abundance of hydrogen is evolved, and a mixed product is obtained, containing, together with unattacked phenol, salicylic acid, oxybenzoic acid, diphenol, and other substances of unknown composition (Barth, *Ann. Ch. Pharm.* clvi. 93). At least half the phenol employed remains unaltered; the amount of acids produced does not exceed 1 p.c. of the phenol decomposed; 12 to 15 p.c. of the phenol employed is obtained in the form of diphenol.

6. When oxidised by *chromic acid* phenol is converted into phenoquinone, $C^6H^4O^4$ (Wichelhaus, *Deut. Chem. Ges. Ber.* v. 248, 846). The first action appears to consist in the production of quinone:

the phenoquinone being formed from this compound and phenol in the following manner:

Phenoquinone is produced, together with hydroquinone and quinhydrone, when quinone is added to a solution of phenol:

7. By the action of *nitrous acid* phenol is converted into nitrosophenol, $C^6H^4.NO.OH$ (Bayer, *Deut. Chem. Ges. Ber.* vii. 967).

8. When a solution of 6 p.c. of *potassium nitrite* in concentrated sulphuric acid is added to a mixture of equal volumes of phenol and concentrated sulphuric acid, the solution at first becomes brown, then green, and finally assumes a magnificent blue colour. The colouring matter is deposited in reddish-brown flocculi on pouring the

solution into water; it has the composition $C^6H^3NO^3 = 3C^6H^4O + HNO^2 - 2OH$ (Liebemann, *ibid.* vii. 248, 1098).

The same compound is produced when nitrosophenol and phenol are mixed and concentrated sulphuric acid is added, and there can be little doubt that the first action of the nitrite mixture is to form nitrosophenol, which then enters into reaction with the unattacked phenol, perhaps in the manner indicated by the following equation:

9. On distilling a mixture of phenol and *lead oxide*, a small portion undergoes conversion into diphenylene oxide, $(C^6H^4)_2O$. At the same time a small quantity of a second body crystallising in needles (m. p. $173^\circ-174^\circ$) is obtained, which probably has the composition $C^{12}H^6O^2$ (Graebe, *ibid.* vii. 396; Bohr a. van Dorp, *ibid.* 398).

10. The crystals obtained, together with phenyl sulphhydrate and sulphide, on distilling phenol with *phosphorus pentasulphide* (Kekulé a. Saueh) are identical with the phenylene sulphide obtained by Stenhouse. The compound, however, is a diphenylene disulphide, $(C^6H^4)_2S_2$, and not phenylene sulphide, C^6H^4S (Graebe, *ibid.* vii. 51, 397).

11. On adding phenol to *diazobenzene sulphate*, phenyl ether or oxide is produced (Hofmeister, *Ann. Ch. Pharm.* clix. 191):

12. When a mixture of *benzyl chloride* and phenol is gently heated with metallic zinc, hydrochloric acid is evolved in abundance and benzyl-phenol is produced (Paternò, *Gazzetta chimica italiana*, ii. 1):

13. When heated with phthalic anhydride and concentrated sulphuric acid, phenol is converted into phenol-phthalein (Bayer, *Deut. Chem. Ges. Ber.* iv. 658)—

14. *Chromic chloride* (chlorochromic anhydride), $C^6O^2Cl^2$, acts violently upon phenol dissolved in glacial acetic acid, producing chiefly tri- and tetra-chloroquinone (Carstanjen, *J. pr. Chem.* [2], ii. 82).

15. *Nitrosyl chloride*, $NOCl$, acts readily upon phenol. According to Tilden (*Chem. Soc. J.* [2], xii. 851), it appears to oxidise the phenol to quinone, which is then converted into chlorinated quinones, the nitrosyl chloride itself suffering reduction, not merely to nitric oxide or nitrogen, but being converted in great part into ammonium chloride.

16. *Pyrosulphuric chloride*, $S^2O^3Cl^2$, at once attacks phenol and forms a mixture of the two isomeric monochlorophenols obtained on chlorinating phenol, with the corresponding chlorophenolsulphonic acids, sulphurous anhydride and hydrochloric acid being evolved (Armstrong and Pike, *Chem. News*, xxix. 283).

17. By heating phenol with carbonic chloride (phosgene) in sealed tubes at $140^\circ-150^\circ$, a mixture of phenyl chlorocarbonate and phenyl carbonate is obtained (Kempf, *J. pr. Chem.* [2], i. 402):

18. According to Dusart a. Bardy (*Compt. rend.* lxxiii. 1379) phenol is converted into monochlorobenzene, C^6H^4Cl , by the action of fuming *hydrochloric acid* at 200° . They also assert that mixtures of phenol and *methylic, ethylic, or amyl alcohol*, saturated with hydrochloric acid, furnish the corresponding mixed ethers when heated in sealed tubes at 100° . These statements, however, appear to require confirmation.

19. On heating phenol with *benzamide*, ammonia and benzoyl-phenol or phenylic benzoate, $C^6H^4.O.CO^2C^6H^5$, are produced; similarly phenol and acetamide yield acetyl-phenol or phenylic acetate, $C^6H^4.O.COCH^3$, and ammonia (Guarreschi, *Ann. Ch. Pharm.* clxxi. 140).

20. A dry mixture of potassium-phenol and *potassium benzoate* yields diphenyl on distillation, $C^6H^4.OK + C^6H^4.CO^2K = (C^6H^4)_2 + K^2CO^3$. An excess of benzoate is desirable, but the amount employed should not be more than double that required by theory. Similarly a mixture of *potassium acetate* and potassium-phenol furnishes

toluene, $C^6H^5.OH^2$, and a mixture of *potassium valerate* and potassium-phenol yields isobutylbenzene, $C^6H^5.C^4H^9$. A mixture of potassium-phenol and *potassium metanitrobenzoate* with sand gave nitrodiphenyl, $C^6H^4.NO^2.C^6H^5$, when carefully distilled. *Potassium oxalate* and potassium-phenol also furnish diphenyl. A mixture of *potassium acetate* and potassium-tribromophenol is said to yield tribromotoluene, $C^6H^2.Br^3.CH^3$ (Pfankuch, *J. pr. Chem.* [2], vi. 97).

21. When *acetanilide* is distilled with sodium-phenol, diphenyl, aniline, acetone, and a very small quantity of a body having the properties of diphenylamine are produced. A trace of the latter body is also obtained on heating *sulphocarbonilide* with sodium phenol (Weith, *Deut. Chem. Ges. Ber.* vi. 966).

22. Berthelot (*Compt. rend.* lxxiii. 663) has determined the heat evolved on neutralising aqueous solutions of phenol and trinitrophenol by the alkaline hydrates. He finds that the heat furnished by the reaction of phenol with the hydrates of potassium, sodium, barium, and calcium is very nearly the same, and that it is scarcely influenced by the amount of water present (see HEAT, p. 620).

Amidophenols. *Para-amidophenol*, $C^6H^4.NH^2.OH$ (1 : 4), first obtained by Fritzsche (*Ann. Ch. Pharm.* cx. 166), by the action of iron and acetic acid on paranitrophenol, is best prepared by reducing paranitrophenol with tin and hydrochloric acid; the excess of acid is removed by evaporating the solution, and after the addition of much water, the tin is precipitated by sulphuretted hydrogen; the solution is concentrated in a current of sulphuretted hydrogen, and then left to crystallise, when para-amidophenol hydrochloride separates in colourless plates (Schmitt a. Cook, *Kekulé Org. Chem.* iii. 61). Alkaline carbonates precipitate para-amidophenol from a solution of the hydrochloride as a brown-red crystalline powder soluble at 0° in 90 pts. of water and 22 pts. absolute alcohol. Para-amidophenol is also obtained on distilling amidosalicylic acid (Schmitt, *Deut. Chem. Ges. Ber.* i. 67). The *hydrochloride* dissolves at 0° in 1.4 pts. of water and 10 pts. of absolute alcohol; the *sulphate* crystallises in thin needles; the *acetate* melts at 183° and dissolves at 0° in 9 pts. of water and 12 pts. alcohol. By the action of benzoyl chloride at 150°, para-amidophenol hydrochloride is converted into benzoyl-para-amidophenol, which melts at 139° with partial decomposition. It is insoluble in water, and but slightly soluble in alcohol; boiling alcohol decomposes it (Morse, *ibid.* vii. 1319).

Orthoamidophenol, $C^6H^4.NH^2.OH$ (1 : 2), is similarly prepared from orthonitrophenol (Schmitt a. Cook). It separates from the hydrochloride in white glistening rhombic plates (Körner), soluble at 0° in 59 pts. water and 23 pts. alcohol. *Orthoamidophenol hydrochloride* crystallises in long needles which dissolve at 0° in 1.25 pt. water and 2.36 pts. alcohol; the *sulphate* forms rhombic prisms; the *acetate* melts at 150°, and dissolves at 0° in 65 pts. water and 40 pts. alcohol. When heated with benzoyl chloride at 150°, orthoamidophenol hydrochloride furnishes benzoyl-orthoamidophenol, $C^6H^3.OH.NH.COC^6H^5$, which crystallises from alcohol in beautiful plates or prisms possessing an extremely pleasant odour. It melts at 103°; it is slowly decomposed by boiling water, in which it is soluble. Fuming nitric acid converts it into dinitrobenzoyl-orthoamidophenol, which forms thin straw-yellow needles melting at 173° (Morse).

Para- and orthoamidophenol hydrochlorides are dissolved by Nordhausen sulphuric acid, with formation of the corresponding amidophenolsulphonic acids (Brackebusch, *ibid.* vi. 396).

Dichlorazophenol.—By the action of potassium permanganate solution and other oxidising agents, the amidophenols are converted into brown humus-like substances, orthoamidophenol being by far the more readily attacked; on treatment, however, of para-amidophenol hydrochloride with bleaching-powder solution, dichlorazophenol is produced, the reaction taking place with such precision that it may be employed for the quantitative analysis of bleaching-powder (Schmitt a. Bennewitz, *J. pr. Chem.* [2], viii. 1):

Orthoamidophenol does not yield a corresponding compound, but is acted upon in a manner not yet understood. To prepare dichlorazophenol, at most 3 grams of para-amidophenol hydrochloride are dissolved in 150 grams of water, and a rather concentrated solution of bleaching-powder is added from a burette. At first, white crystalline flakes separate, which redissolve on shaking, and the solution assumes a deep violet colour; on further addition of the bleaching-powder, a point is reached where the separated dichlorazophenol no longer redissolves, but the liquid becomes paler and suddenly turns yellow. The reaction is then completed. The product is separated by filtration, and after washing with water, dried over sulphuric acid. Dichlorazophenol

is sparingly soluble in cold water, but freely in boiling water, alcohol, benzene, ether, and glacial acetic acid; it crystallises in tufts of long yellow needles. It melts at 86° , and decomposes at a slightly higher temperature; it is extremely volatile, and has a very persistent odour like that of quinone. When reduced by tin or zinc and hydrochloric acid, it furnishes para-amidophenol. On treatment with sulphurous acid or hydrogen-sodium sulphite, it is entirely converted into para-amidophenolsulphonic acid:

Paradiazophenol hydrochloride, $\text{C}^6\text{H}^4\text{N}^2\text{Cl}$.—If absolute alcohol, saturated with nitrous anhydride, be poured over dry para-amidophenol hydrochloride, the mixture being carefully cooled by ice-water, an indigo-blue solution is at first produced which afterwards becomes brown; if sufficient ether to produce a milkiness in the liquid be then added, the whole after a short time becomes a solid mass from the separation of the diazohydrochloride. It crystallises in long colourless needles, difficultly soluble in alcohol.

Orthodiazophenol hydrochloride, $\text{C}^6\text{H}^4\text{N}^2\text{Cl}$, is similarly prepared from orthoamidophenol hydrochloride. It crystallises in colourless well-formed rhombohedrons, much more soluble in alcohol than the isomeric compound. Both these substances are extremely unstable (Schmitt, *Deut. Chem. Ges. Ber.* i. 67).

On heating a concentrated solution of sodium hydrogen sulphite, to which an ortho- or para-diazophenol salt has been added, to boiling, the diazophenol quickly dissolves without nitrogen being evolved; on cooling, the sodium salt of the product separates out, but it is better to add a concentrated solution of potassium chloride, and to recrystallise the precipitated potassium salt several times from dilute alcohol. **Potassium orthodiazophenol sulphite**, $\text{C}^6\text{H}^4(\text{OH})\text{N}^2\text{SO}^3\text{K} + \text{OH}^2$, thus prepared, crystallises in small golden-yellow scales; the para-diazo-derivative forms pale-yellow anhydrous needles (Schmitt a. Glutz, *Deut. Chem. Ges. Ber.* ii. 51).

Diamidophenol, $\text{C}^6\text{H}^4(\text{NH}^2)_2\text{OH}$ (1 : 2 : 4).—Gauhe (*Ann. Ch. Pharm.* cxlvii. 66), by the action of hydriodic acid on α -dinitrophenol, obtained the hydriodide of a base which he regards as a diamidobenzene different from the two phenylenediamines then known. It does not agree, however, in properties with the third diamidobenzene since discovered by Griess, and there is reason therefore to suppose that, although both the hydriodide and sulphate gave on analysis numbers which correspond with those required by theory for a diamidobenzene, Gauhe's product was really diamidophenol. The hydriodide forms white needles; the sulphate, magnificent rhombic plates; the hydrochloride, white needles. These salts are partially decomposed on exposure to the air; all attempts to separate the free base from them by an alkali were unsuccessful, the solution at once becoming red-brown, and after a short time depositing brown flocculi. The addition of ferric chloride caused a deep red coloration.

Bromophenols. **Parabromophenol**, $\text{C}^6\text{H}^4\text{Br.OH}$ (1 : 4).—Körner (*Gazzetta chimica italiana*, 1874, iv. 387), and Fittig a. Mager (*Deut. Chem. Ges. Ber.* vii. 1176) have prepared this compound from parabromaniline (m.p. 66.4° Körner, 63° Fittig a. Mager). Parabromaniline nitrate, mixed with an excess of nitric acid, was treated with nitrous anhydride; the resulting diazobromobenzene nitrate was converted into sulphate by the addition of sulphuric acid, and the sulphate precipitated by alcohol and ether; the crystallised diazobenzene sulphate was then dissolved in a large quantity of water, and the solution gently heated. The bromophenol produced was extracted with ether and purified by distillation. Parabromophenol is also obtained by distilling bromosalicylic acid with burnt lime (Huebner a. Brenken, *ibid.* vi. 170). The product is an oil of which the greater part distils over at about 235° , and is easily converted by cooling into a crystalline mass; it may be purified by pressing and recrystallisation from chloroform. Huebner a. Brenken have shown that parabromophenol may be readily prepared from phenol by the following process:—The calculated quantity of bromine dissolved in 200 grams of glacial acetic acid is added to a well-cooled solution of 100 grams of phenol in 300 of acetic acid; a strong current of carbonic anhydride is then passed through the liquid to remove the hydrobromic acid; and subsequently the solution is cooled in a mixture of ice and salt. The crystals which separate after a time are removed by filtration in a vacuum-filter, pressed until quite dry and as free as possible from acetic acid, and then several times carefully fused and again allowed to solidify, in order to remove adherent hydrobromic acid; after which they may be distilled, the portion boiling at 235° – 236° being collected apart and several times recrystallised from chloroform.

Parabromophenol crystallises in large, colourless, transparent (probably) monoclinic

crystals, which become pink on long exposure to the air; it melts at 66.4° (Körner), 63°-64° (Huebner, Fittig a. Mager), and distils, undergoing scarcely any decomposition, at 238° (Fittig), 235°-236° (Huebner a. Brenkon). It dissolves in a large quantity of cold water, and more readily in hot water; it is easily soluble in alcohol, chloroform, and acetic acid. On nitration it yields Brunck's parabromonitrophenol, melting at 88° (Huebner a. Brenken, Körner), or bromodinitrophenol, melting at 76° (Körner, Armstrong), according to the amount of nitric acid employed. When fused with potassium hydrate it yields resorcin free from its isomerides (Fittig a. Mager).

Metabromophenol, $C^6H^4Br.OH$ (1 : 3), has been obtained by Körner (*loc. cit.*) and by Wurster a. Nölting (*Deut. Chem. Ges. Ber.* vii. 904) from metabromaniline by Griess's method. It is an oil boiling at 227°-229° (W. u. N.). According to Wurster a. Nölting, it is converted into resorcin on fusion with potassium hydrate. On treatment with bromine in excess it yields tetrabromophenol, and with nitric acid furnishes, amongst other products, a dinitrobromophenol melting at 91.5° (Körner).

Metabromophenol, according to Körner's observations, may also be produced by the direct action of bromine on phenol, but it is not known at present what are the circumstances favourable to its production, nor indeed even whether it is always present in the crude bromophenol. Körner converted the bromophenol which he prepared by passing a current of air laden with bromine into cooled phenol (1st *Suppl.* 907) into the methyl ether, $C^6H^4Br.O.CH^3$, by acting upon its potassium derivat with methyl iodide, and from this he obtained, by the action of carbonic anhydride and sodium, a methoxybenzoic acid identical with that prepared by Graebe and Schultzen from ordinary oxybenzoic acid ($OH : COOH = 1 : 3$):

By the action of sodium and methyl iodide on the same methyl-bromophenol a methyl-cresol was obtained, $(C^6H^4Br.OCH^3 + CH^3I + 2Na = C^6H^4.CH^3.OCH^3 + NaBr + NaI)$, also yielding methoxybenzoic acid on oxidation (*Bull. de l'Acad. Belg.* 1867; *Zeitschr. f. Chem.* 1868, 326). In his recent memoir (*Gazzetta chimica italiana*, iv. 389) Körner states that he has re-examined specimens of the methoxybenzoic acid and methyl cresol prepared in 1866, which he had preserved, and convinced himself anew of the correctness of his observations; at the same time he mentions that he was unable to obtain similar results with a bromophenol prepared under conditions apparently identical with those previously observed by him in its preparation.

Orthobromophenol, $C^6H^4Br.OH$ (1 : 2), has been prepared by Körner (*loc. cit.*) from orthobromaniline by Griess's method, and by the decomposition of the platinobromide of the diazophenol formed from orthoamidophenol. It is a colourless oil. On nitration it is ultimately converted into bromo- α -dinitrophenol (Körner; Armstrong).

Orthobromophenol is always produced by the action of bromine on phenol, and the acetic acid solution which drains from the crystals of parabromophenol prepared by Huebner a. Brenken's method contains it in considerable quantity.

Chlorophenols. *Parachlorophenol*, $C^6H^4Cl.OH$ (1 : 4), which was first obtained in a state of purity by the action of sulphuric chloride, SO^2Cl^2 , on phenol, is formed when the platinochloride of paradiaphenol is submitted to distillation (Schmitt, *Deut. Chem. Ges. Ber.* i. 67), and from parachloraniline (m. p. 70°) by Griess's method (Beilstein a. Kurbatow, *ibid.* vii. 1395). It may also readily be prepared by passing chlorine into phenol, mixed with sufficient water to prevent its solidifying and cooled with ice, until it has increased in weight by the calculated amount; the product is washed with water and a little dilute potassium hydrate solution to remove hydrochloric acid, dried by calcium chloride and anhydrous cupric sulphate, and then fractionally distilled. The portion boiling at 215°-220° solidifies at about 0°, but melts again at 8°; by allowing the liquid portion to drain away, however, it is possible to raise the melting point almost to that observed by Dubois (Petersen a. Baehr-Predari, *Ann. Ch. Pharm.* clvii. 123).

Parachlorophenol melts at 41° (Dubois), 37° (Beilstein a. Kurbatow), and boils at 218° (Petersen a. Predari), 217° (Beilstein a. Kurbatow). When fused with potassium hydrate, the chlorophenol boiling at 218° prepared from phenol furnishes chiefly hydroquinone and traces of resorcin, according to Petersen a. Baehr-Predari (*loc. cit.* and *Deut. Chem. Ges. Ber.* vii. 61), but Faust states that resorcin only is obtained (*ibid.* vi. 1022). Parachlorophenol yields ordinary dichlorobenzene (m. p. 53°, b. p. 172°) when distilled with phosphorus pentachloride (Beilstein a. Kurbatow). Dilute nitric acid converts it into parachloronitrophenol melting at 86.5° (Beilstein a. Kurbatow). *Methyl-parachlorophenol*, $C^6H^4Cl.O.CH^3$, boils at 198°-202°, and does not solidify at -18°; *ethyl-parachlorophenol*, $C^6H^4ClO.C^2H^5$, melts at 21° and boils at 210°-212° (Beilstein a. Kurbatow).

Metachlorophenol, $C^6H^4Cl.OH$ (1 : 3), is obtained by Griess's method from meta-

chloraniline (from dinitrobenzene); it is an oil boiling at 214° (Beilstein a. Kurbatow, *loc. cit.*)

Orthochlorophenol, $C^6H^4Cl.OH$ (1 : 2).—Beilstein a. Kurbatow (*loc. cit.*) have prepared this modification from orthochloraniline by Griess's method, and it was previously obtained by Faust a. Müller (*Deut. Chem. Ges. Ber.* v. 777; *Ann. Ch. Pharm.* clxxiii, 303), by distilling orthodiazophenol platinochloride. On passing chlorine into 500 grams of phenol without cooling until the weight is increased by 200 grams, and fractioning the product, which boils at 175° – 220° , a portion is obtained boiling constantly at 175.5° – 177° , consisting of orthochlorophenol (Faust a. Müller, *loc. cit.*) It is a colourless, oily liquid, which has a peculiar unpleasant odour, and does not solidify at -15° (Faust a. Müller). According to Kramers (*Ann. Ch. Pharm.* clxxiii, 331) the yield of orthochlorophenol is about one-third of the weight of phenol employed; he describes it as a colourless oil, boiling constantly at 176° – 177° under a pressure of 760 mm., the mercury-column in the thermometer being wholly immersed in the vapour. On cooling it to -12° , he found that it solidifies to a mass exactly resembling pure crystalline phenol; when removed from the refrigerating mixture it fuses, and a thermometer immersed in the fusing mass exhibits constantly the temperature 7° . When fused with potassium hydrate, orthochlorophenol yields pyrocatechin, the conversion taking place far more readily than that of parachlorophenol into resorcin (Faust a. Müller, *loc. cit.*; Petersen, *Deut. Chem. Ges. Ber.* vi. 368). By the action of dilute nitric acid it furnishes orthochloroparanitrophenol, melting at 110° – 111° , and orthochlorororthonitrophenol, melting at 70° (Faust a. Müller; Beilstein a. Kurbatow). When distilled with phosphorus pentachloride it is converted into orthodichlorobenzene, boiling at 179° ; sp. gr. 1.3278 at 0° (Beilstein a. Kurbatow). **Ethyl-orthochlorophenol**, $C^6H^4Cl.O.C^2H^5$, is a liquid boiling at 208° – 208.5° (Beilstein a. Kurbatow).

Pentachlorophenol, $C^6Cl^5.OH$. **Perchlorophenol**.—To prepare this compound, chlorine is passed into a mixture of 3 pts. of phenol and 1 pt. of antimonious chloride, which is heated at first on the water-bath and afterwards in a salt-bath, until all action ceases. The resulting mass is boiled with sodium hydrate solution, and the hot filtrate supersaturated with hydrochloric acid; the precipitated crude pentachlorophenol is then distilled in a current of superheated steam (180° – 200°), and recrystallised from petroleum spirit (Merz a. Weith, *ibid.* v. 458).

Pentachlorophenol crystallises in long colourless glistening needles, and is very soluble in alcohol and ether, moderately soluble in benzene, and slightly soluble in cold petroleum spirit. It melts at 186° – 187° . When cold it has no odour, but when heated it has an intensely sharp odour and causes coughing. Pentachlorophenol dissolves, although slowly, in cold solutions of potassium or sodium hydrate; it is almost entirely precipitated, however, from dilute alkaline solutions by carbonic anhydride. **Potassium pentachlorophenol**, $C^6Cl^5.OK$, crystallises from ether-alcohol in long white needles; it is easily soluble in anhydrous alcohol, and even in ether. **Sodium pentachlorophenol** closely resembles the potassium-derivative. **Ammonium pentachlorophenol**, $C^6Cl^5.ONH^4$, crystallises from a hot ammoniacal solution in very long thin pliable needles; it scarcely dissolves in water, although it is readily soluble in alcohol. Pentachlorophenol is only very slowly attacked by nascent hydrogen from sodium-amalgam and water. Concentrated nitric acid converts it, even in the cold, into tetrachloroquinone:

When distilled with phosphorus pentachloride it furnishes hexachlorobenzene. Potassium hydrate has scarcely any action below 200° ; at 230° – 240° humus-like substances are largely produced, free from chlorine and insoluble in water; the alkaline solution contains a large quantity of oxalate.

Pentachlorophenol is decomposed on distillation, hydrochloric acid being evolved, and tetrachlorophenylene oxide is produced:

Potassium pentachlorophenol undergoes a corresponding decomposition when heated. The product is powdered and washed with alcohol, crystallised from boiling nitrobenzene, and then several times recrystallised from hot turpentine. **Tetrachlorophenylene oxide** is scarcely dissolved by alcohol, ether, chloroform, or carbon sulphide, but is readily soluble in boiling nitrobenzene, and moderately soluble in hot turpentine. It forms broad white needles like benzoic acid. It melts at about 320° , and distils undecomposed at a temperature far above that at which mercury boils. On account of its high melting and boiling points, Merz a. Weith are inclined to represent it by the formula:

It is not attacked by sodium-amalgam and water, or by phosphorus pentachloride—even at 240°–250°. Boiling concentrated nitric acid very slowly decomposes it, chlorine and carbonic anhydride being evolved.

Iodophenols (Lobanoff, *Deut. Chem. Ges. Ber.* vi. 1251). The iodophenol prepared by Körner's method (1st *Suppl.* 909) is a mixture of the three isomeric mono-iodophenols. When it is distilled in a current of steam, first a liquid iodophenol passes over, then a solid iodophenol, and finally tri-iodophenol; and the residue contains a considerable quantity of the latter, which may be extracted by alcohol. The third modification, which is easily soluble in water, is found in part in the aqueous solution from which the crude iodophenol is precipitated, in part in the aqueous distillate, and in part in the alcoholic solution from which the tri-iodophenol crystallises. In order to separate it, these solutions are rendered alkaline with potassium hydrate, concentrated by evaporation, and then supersaturated with hydrochloric acid. The precipitated iodophenol is purified by recrystallisation. It crystallises from ether in needles, from alcohol in large six-sided plates, and from carbon sulphide in short thick prisms; it dissolves well in water and ether, and very easily, in alcohol and carbon sulphide. It melts at 89°. The second solid iodophenol, which melts at 64°–66°, is difficultly soluble in water, but easily soluble in alcohol and ether, and crystallises in flat glistening needles. The liquid iodophenol does not solidify at –23°. Iodine is not separated by chlorine or nitric acid from the iodophenol melting at 89°, or from that which melts at 64°–66° by chlorine; nitric acid, however, liberates iodine from this modification. The liquid iodophenol is decomposed both by chlorine and by nitric acid.

The constitution of these compounds has not yet been determined, but a comparison of Lobanoff's results with those of Körner renders it probable that the modification melting at 64°–66° is *paraiodophenol* (1 : 4), identical with Körner's *orthoiodophenol*, whilst that melting at 89° is *metaiodophenol* (1 : 3), identical with Körner's *paraiodophenol* from dinitrobenzene; the liquid modification being *orthoiodophenol* (1 : 2), identical with Körner's *metaiodophenol*.

Nitrophenols. *Paranitrophenol*, $C^6H^4(NO^2)OH$ (1 : 4).—The volatile non-modification of nitrophenol, which has long been known as *ortho-* and *isonitrophenol*, has recently been shown to be a member of the *para* series. It is produced: 1. When α -nitrochlorobenzene (m. p. 85°) from chlorobenzene is heated with potassium hydrate solution at 130° (Engelhardt a. Latschinow, *Deut. Chem. Ges. Ber.* iii. 423). 2. When α -nitrobromobenzene (m. p. 125°) from bromobenzene is heated with potassium hydrate solution (von Richter, *ibid.* iv. 460). 3. By heating nitroacetanilide from acetanilide with concentrated sodium-hydrate solution until ammonia ceases to be evolved (Wagner, *ibid.* vii. 76). 4. By decomposing diazonitrobenzene nitrate, prepared from the nitraniline obtained from acetanilide by boiling with water (Fittig, *ibid.* vii. 280). 5. By dry distillation of nitrosaliclic acid mixed with powdered pumice (Schmitt a. Cook, *Kekulé Org. Chem.* iii. 41). 6. By oxidation of nitrosophenol (Bayer, *Deut. Chem. Ges. Ber.* vii. 965).

Pure paranitrophenol melts at 114°. Salkowski (*ibid.* vii. 45) has converted it into anisic or methyl-*para*-oxybenzoic acid in the following manner:—Silver paranitrophenol was treated with methyl iodide, and the resulting methyl-paranitrophenol or paranitro-anisol, $C^6H^4.NO^2.OCH^3$, reduced to methyl-*para*-amidophenol or *para*-amidoanisil; the latter was then converted by Griess's method into the *diaz*-*perbromide*, which was distilled with lime. Methyl-*para*-bromophenol was then obtained, which, when acted upon by methyl-iodide and sodium, gave methyl-*para*-cresol, $C^6H^4.OH^2.OCH^3$, yielding anisic acid, $C^6H^4.OCH^3.CO^2H$, on oxidation with potassium dichromate and glacial acetic acid.

Salkowski (*ibid.* 1008) also found that when the *paradiaz*oisil sulphate from *para*-amidoanisil, prepared as above described, is heated with water, hydroquinone is produced. The *paradiaz*oisil sulphate and nitrate obtained by the action of nitrous acid on *para*-amidoanisil sulphate or nitrate in presence of a small quantity of water are remarkably stable substances; on concentrating the solution by slow evaporation on the water-bath at a low temperature, they separate in broad flat needles. They are only very slowly decomposed when boiled with water or dilute acids; the decomposition is complete, however, after heating for some hours at 140° in sealed tubes, position is complete, however, after heating for some hours at 140° in sealed tubes, the greater part being converted into a brown viscid substance—probably a methyl ether of hydroquinone—and only the smaller part into hydroquinone. On heating *para*-nitroanisil with aqueous ammonia at 170°–200°, *paranitraniline* or *paranitro*-*amido*benzene, identical with that which is obtained from acetanilide, is formed (Salkowski, *Ann. Ch. Pharm.* lxxiv. 281). When distilled with phosphorus pentachloride, *paranitrophenol* yields α -chloronitrobenzene (m. p. 85°) according to Engelhardt a. Latschinoff (*Deut. Chem. Ges. Ber.* iii. 200). On digestion with fuming sulphuric acid, it is converted into *paranitrophenolsulphonic acid* (Post, *ibid.* v. 852; vi. 396).

Metanitrophenol, $C^6H^4(NO^2)OH$ (1 : 3), is produced on heating the diazonitrobenzene nitrate prepared from the nitraniline from ordinary dinitrobenzene (m. p. 87°) with water. The solution is filtered from the resin, and shaken with ether; on distilling off the ether, an oil remains, which gradually crystallises when exposed over sulphuric acid. It may be purified by recrystallisation from boiling water or alcohol. Metanitrophenol forms hard, compact, almost colourless crystals, melting at $95^\circ-96^\circ$; it is moderately soluble in cold water, and readily soluble in boiling water and alcohol. It scarcely volatilises in a current of steam. Metanitrophenol has a great tendency to remain liquid; when only slightly warmed with water it melts, and always separates from the aqueous solution as an oil, which may remain for days under the liquid without solidifying, but at once crystallises on the addition of a trace of the solid. Also when cold alcohol is poured on the crystals they immediately liquefy, and it regularly separates from the alcoholic solution as an oil (Fittig a. Bantlin, *ibid.* vii. 179). Potassium metanitrophenol crystallises in magnificent long glistening needles, which appear deep red so long as they are surrounded by liquid, but orange after drying; it is very soluble in water and alcohol.

Orthonitrophenol, $C^6H^4(NO^2)OH$ (1 : 2).—This modification, commonly known as volatile nitrophenol, is produced:—1. When the γ -nitrobromobenzene (m. p. $37^\circ-38^\circ$), formed simultaneously with α -nitrobromobenzene on nitration of bromobenzene, is heated with potassium hydrate solution in sealed tubes (Zincke a. Walker, *ibid.* v. 114); and 2. When the corresponding nitrochlorobenzene from chlorobenzene is similarly treated (Engelhardt a. Latschinoff, *ibid.* iii. 423).

When the orthonitranisol, $C^6H^4.NO^2.OCH^3$, from orthonitrophenol, is heated with aqueous ammonia in sealed tubes at about 200° , it is converted into nitraniline (m. p. 61°), identical with that obtained by the action of ammonia on γ -nitrobromobenzene (m. p. $37^\circ-38^\circ$) (Salkowski, *Ann. Ch. Pharm.* clxxiv. 277). It furnishes the corresponding nitrochlorobenzene when distilled with phosphorus pentachloride (Engelhardt a. Latschinoff, *Deut. Chem. Ges. Ber.* iii. 200). When acted upon by nitric acid it yields two isomeric dinitrophenols (Huebner a. Schneider, *Ann. Ch. Pharm.* clxvii. 89)*. Similarly, when acted upon by chlorine, bromine, and sulphuric acid, it furnishes two isomeric chloronitro-, bromonitro- and sulphonitrophenols—nitrophenol-sulphonic acids (Armstrong, Prevost a. Brown, *Deut. Chem. Ges. Ber.* vii. 922); and, according to Busch (*ibid.* 460) a mixture of two isomeric iodonitrophenols on treatment with iodine. When oxidised by permanganic acid it is converted into dinitrophenol (Goldstein, *ibid.* vii. 734):

Dinitrophenols.— α -Dinitrophenol, $C^6H^4(NO^2)_2OH$ (1 : 2 : 4)*, is obtained in a state of purity by the action of nitric acid on paranitrophenol (1 : 4), and also on warming dinitroamidophenol or picramic acid with ethyl nitrite, and together with β -dinitrophenol by the action of nitric acid on orthonitrophenol (1 : 2). It is also produced when dinitrochlorobenzene (m. p. 50°) from chlorobenzene, and dinitrobromobenzene (m. p. 72°) from bromobenzene, are heated with potassium or sodium hydrate solution (Clemm, *J. pr. Chem.* [2], i. 145; Engelhardt a. Latschinoff, *Deut. Chem. Ges. Ber.* iii. 97). When distilled with phosphorus pentachloride, on the other hand, α -dinitrophenol yields dinitrochlorobenzene melting at $48^\circ-49^\circ$ (Clemm, Engelhardt a. Latschinoff, *loc. cit.*). The dinitraniline (m. p. 175°) obtained by heating this dinitrochlorobenzene with ammonia, which is identical with that produced on similarly treating α -dinitranisol, $C^6H^4(NO^2)_2.OCH^3$, is converted into ordinary dinitrobenzene (m. p. 87°) by the action of ethyl nitrite (Rudnew, *Deut. Chem. Ges. Ber.* iv. 409; Salkowski, *Ann. Ch. Pharm.* clxxiv. 263).

Pure α -dinitrophenol melts at $113^\circ-114^\circ$; it crystallises from water in rectangular striated yellowish-white plates, which are usually united in fern-like forms. Characteristic of α -dinitrophenol is the circumstance that its metallic derivatives are capable of crystallising with varying amounts of water (*vide* β -dinitrophenol). Ordinary trinitrophenol (picric acid) alone is produced when α -dinitrophenol is treated with nitric acid (Huebner a. Schneider).

α -Dinitrophenetol, $C^6H^4(NO^2)_2.OC^2H^5$, from silver α -dinitrophenol and ethyl iodide, melts at 84° (Salkowski, *loc. cit.*)

β -Dinitrophenol, $C^6H^4(NO^2)_2OH$ (1 : 2 : 6), is formed, together with α -dinitrophenol, on nitrating orthonitrophenol (1 : 2). The following are the details of its preparation as given by Huebner a. Schneider, by whom it was first made known (*Ann. Ch. Pharm.* clxvii. 80). The orthonitrophenol, in quantities not exceeding 20–25 grams, is placed in a capacious flask together with an equal weight of nitric acid (sp. gr. 1.36), and the mixture is carefully warmed on the water-bath until the reaction commences, which

* In this representing the constitution of the phenol-derivatives the OH-group is throughout this article supposed to occupy the position 1.

is extremely violent, but of short duration. The product, which is at first oily but soon solidifies, is a mixture of the two dinitrophenols with trinitrophenol and unattacked nitrophenol. After being washed with cold water until free from acid, it is introduced into a flask with water, and heated in a current of steam until the ortho-nitrophenol is entirely removed; it is then boiled with water and an excess of barium carbonate, the solution filtered, and the residue several times extracted with boiling water. As soon as the liquid has cooled to 40°, the almost pure β -salt which separates is rapidly removed by filtration; on further cooling the filtrate yields a mixture of the α - and β -salt, which is also filtered off, and the mother-liquor then contains barium di- and trinitrophenol. Barium β -dinitrophenol is very slightly soluble in water at 30°–40°, but somewhat more soluble in boiling water; the α -salt, however, is easily soluble under these conditions. The two salts may therefore be separated without difficulty by treatment with warm water; but, according to Huebner a. Schneider, the separation is greatly facilitated by the use of 90 p.c. alcohol, which dissolves only traces of the β -salt, but in which the α -salt dissolves with moderate readiness. Salkowski (*Ann. Ch. Pharm.* clxiv. 270) converts the mixed barium salts into potassium salts by potassium carbonate, and removes the greater part of the α -salt by crystallisation; the mother-liquor is then heated to 40°–50°, and precipitated by barium chloride, whereby only β -barium dinitrophenol is thrown down. This may be purified by a single recrystallisation after washing with cold water; or, in the case of large quantities, it is converted into potassium salt, and this is recrystallised. Körner (*Gazzetta chimica italiana*, 1874, 325) crystallises the potassium salts from water, and then exposes the mixture to the sun's rays for some days; the α -salt crumbles down to a powder, and may be separated mechanically from the β -salt, which is purified by recrystallisation.

β -Dinitrophenol crystallises from water in fine, short, pale-yellow needles, pointed at the ends; from chloroform it separates in long coarse needles. It is more soluble in cold water, though less soluble in boiling water, than α -dinitrophenol; it is very soluble in chloroform, benzene, ether, and boiling alcohol. It melts at 63°–64°. The dinitroaniline (m. p. 138°) obtained on heating β -dinitroanisole, $\text{C}_6\text{H}_4(\text{NO}_2)_2\text{OCH}_3$, from β -dinitrophenol with aqueous ammonia at 130°, is converted into ordinary dinitrobenzene (m. p. 87°) when heated with ethyl nitrite (Salkowski, *Ann. Ch. Pharm.* clxiv. 274). The dinitroaniline from β -dinitrophenol is much less readily decomposed by ethyl nitrite than that derived from the α -dinitrophenol; in the latter case it is merely necessary to heat the substances together in a flask, but in the former they must be digested in sealed tubes at 120° (Salkowski). Concentrated nitric acid converts β -dinitrophenol into ordinary trinitrophenol (Huebner a. Schneider).

The metallic derivatives of β -dinitrophenol differ considerably in composition, appearance, and solubility from those of α -dinitrophenol; this will be evident on inspection of the table on page 910.

β -Dinitroanisole, $\text{C}_6\text{H}_4(\text{NO}_2)_2\text{OCH}_3$, crystallises from alcohol in colourless needles, melting at 116°, soluble in 64.2 pts. of 95 volume p.c. alcohol at 21° (α -dinitroanisole melts at 87°, and dissolves in 110 pts. of alcohol at 21°). β -Dinitrophenetole, $\text{C}_6\text{H}_3(\text{NO}_2)_2\text{OC}_2\text{H}_5$, also crystallises in colourless needles which melt at 57°–58° (Salkowski, *Ann. Ch. Pharm.* clxiv. 273).

Trinitrophenol, $\text{C}_6\text{H}_3(\text{NO}_2)_3\text{OH}$ (1 : 2 : 4 : 6), is obtained by nitration of both α - and β -dinitrophenol. It is also formed when trinitrochlorobenzene (m. p. 82°–83°) is boiled with sodium hydrate or carbonate solution (Engelhardt a. Latschinoff, *Deut. Chem. Ges. Ber.* iii. 98; Clemm, *J. pr. Chem.* [2] i. 145). According to E. a. L. the conversion of trinitrochlorobenzene to trinitrophenol is effected by boiling with water, but Clemm denies this. Trinitrochlorobenzene is readily obtained by the action of phosphorus pentachloride on trinitrophenol. An intimate mixture of at most 100 grams of the latter with 200 grams of chloride is very cautiously warmed in a large retort or flask connected with a wide reversed condenser. As soon as the mass begins to liquefy, the source of heat is removed; the reaction which then takes place is exceedingly violent. The liquid product is afterwards gently boiled for some time the phosphorus oxychloride is then distilled off, and the mass thrown into a large quantity of water. When solid, it is pulverised, washed with ether, and recrystallised from alcohol, and finally from petroleum spirit, in which it is only very slightly soluble, however. The trinitroaniline obtained by heating trinitrochlorobenzene (Clemm) or trinitroanisole, $\text{C}_6\text{H}_4(\text{NO}_2)_3\text{OCH}_3$ (Salkowski, *Deut. Chem. Ges. Ber.* iv. 873), with ammonia is not decomposed by ethyl nitrite even at 160° (v. Meyer, *Ann. Ch. Pharm.* clxv. 187).

The chlorodinitrophenol produced by Stenhouse's reaction by heating trinitrophenol with iodine chloride and water (1st Suppl. 914) consists of chloro- α -dinitrophenol (m. p.

Metallic derivatives of α -dinitrophenol	Metallic derivatives of β -dinitrophenol

110° – 111°) mixed with a relatively small quantity of Dubois' parachloro- β -dinitrophenol (Petersen, *Deut. Chem. Ges. Ber.* vi. 368; Armstrong, *ibid.* 650). When trinitrophenol is similarly acted upon by iodine bromide, it yields bromo- α -dinitrophenol melting at 117° (Armstrong, *loc. cit.*)

By heating with acetic anhydride trinitrophenol is converted into acetyl-trinitrophenol, $\text{C}^6\text{H}_2(\text{NO}_2)_3\cdot\text{O}\cdot\text{C}^6\text{H}_3\text{O}$; it is a crystalline pale-yellow substance, which melts at 76° – 76° (Tommasi a. David, *Compt. rend.* lxxvii. 207).

Diamidodinitrophenol, $\text{C}^6\text{H}_3(\text{NO}_2)(\text{NH}_2)_2\text{OH}$ (1 : 2 : 4 : 6).—This compound is obtained by reducing trinitrophenol with aqueous ammonium sulphide (Griess, *Ann. Ch. Pharm.* cliv. 202). To prepare it, pulverised trinitrophenol is mixed with a large excess of dilute aqueous ammonia and a rapid current of hydrogen sulphide then passed in, the mixture being shaken from time to time. The conversion is complete, and the passage of the gas must be stopped so soon as very dilute hydrochloric acid fails to produce a precipitate in a portion of the solution which has previously been concentrated and filtered from the separated sulphur. The liquid is then concentrated somewhat by evaporation, filtered from the sulphur, and supersaturated with acetic acid. The brownish needles of diamidodinitrophenol which separate are obtained perfectly pure after a single recrystallisation from water to which a little animal charcoal is added. Diamidodinitrophenol crystallises in long dark-yellow needles or narrow plates. It is somewhat more soluble in alcohol than in water, but very slightly soluble in ether. The air-dry substance contains a molecule of water of crystallisation, which is readily given off above 100° .

Diamidodinitrophenol has far stronger basic properties than amidodinitrophenol (picramic acid), which dissolves only in concentrated acids, the resulting compounds being decomposed on the addition of water. Diamidodinitrophenol is soluble even in very dilute solutions of the mineral acids, forming stable compounds; like amidodinitrophenol, it does not unite with organic acids, however. *Diamidodinitrophenol sulphate*, $[\text{C}^6\text{H}_3(\text{NH}_2)_2(\text{NO}_2)\text{OH}]^+\cdot\text{H}_2\text{SO}_4 + 5\text{H}_2\text{O}$, crystallises in long yellowish needles or columns, and is difficultly soluble even in boiling water. *Diamidodinitrophenol hydrochloride* forms delicate four-sided plates usually of a greenish colour. It is very soluble in cold water and alcohol, but is separated from the latter solution in crystals by ether. Platinum chloride produces no precipitate, even in very concentrated solutions of this salt.

The metallic derivatives of diamidodinitrophenol are far less stable than those of amidodinitrophenol, and undergo oxidation when exposed to the air in a moist state.

Those which are dissolved by water are more soluble than the corresponding amidodinitrophenol derivatives. *Barium diamidonitrophenol*, $[\text{C}_6\text{H}_3(\text{NH})_2(\text{NO})_2\text{O}]^{2+}\text{Ba} + 2\text{H}_2\text{O}$, separates in ruby-red needles on the addition of barium chloride to a solution of ammonium diamidonitrophenol. If recrystallised from water, in which it is moderately soluble, it is obtained in almost black glistening prisms. Silver diamidonitrophenol separates as a reddish-yellow precipitate which rapidly blackens on the addition of silver nitrate to a solution of ammonium diamidonitrophenol. The zinc derivative resembles the silver derivative, but is far more stable. Basic lead acetate produces a reddish-brown precipitate in an aqueous solution of diamidonitrophenol.

The formation of diamidonitrophenol is preceded by that of amidodinitrophenol, according to Griess; but his experiments show that, when the reduction of trinitrophenol takes place in an alcoholic solution, as in the preparation of amidodinitrophenol by Girard's method, it has but little tendency to extend to more than one of the three nitro-groups. Aqueous ammonium sulphide scarcely acts upon diamidonitrophenol in the cold, but when heated to boiling converts it completely into a blue-black, neutral, amorphous body, which is insoluble in all the ordinary solvents, but is dissolved by strong warm sulphuric acid (Griess).

Nitrosophenols. *Paranitrosophenol*, $\text{C}_6\text{H}_4(\text{NO})\text{OH}$ (1 : 4) (Baeyer a. Caro, *Deut. Chem. Ges. Ber.* vii. 983), is produced when nitrosodimethylaniline is boiled with sodium hydrate solution :

and by the action of nitrous acid on phenol.

Baeyer a. Caro prepare nitrosodimethylaniline by adding 100 pts. of amyl nitrite to a mixture of 50 pts. of dimethylaniline with 100 pts. of concentrated hydrochloric acid and 750 pts. of a mixture of 1 vol. of hydrochloric acid with 2 vols. of alcohol, which is well cooled with ice. After a short time yellow needles of nitrosodimethylaniline hydrochloride separate; as soon as these no longer increase in quantity, the mass is thrown on a vacuum-filter, and washed with ether-alcohol.

To prepare the nitrosophenol, a mixture of 90 pts. water with 10 pts. sodium hydrate solution (sp. gr. 1.25), is heated to boiling in a flask connected with a reversed condenser, and 2 pts. nitrosodimethylaniline hydrochloride is gradually added, care being taken each time to await the disappearance of the oily drops of the base before adding a fresh quantity of the salt. The boiling is continued until the dark greenish-yellow colour has entirely disappeared and changed to reddish-yellow. The greater part of the dimethylamine passes over during the boiling, and should be collected in hydrochloric acid. To obtain the nitrosophenol the solution is well cooled, rendered slightly acid with sulphuric acid, and extracted with ether; on distilling off the ether it remains in the form of a brown crystalline mass.

Phenol is converted into nitrosophenol in the following manner:—5 pts. of phenol and 20 pts. of potassium nitrite are dissolved in 1,000 pts. of water, and the solution cooled as well as possible with ice-water; 10–12 pts. of ordinary acetic acid, diluted with 10 vols. of water, is then added little by little and with constant shaking. After 12–16 hours the brown liquid is filtered to separate a small quantity of resin, and extracted with ether; in order, however, to avoid the action of any excess of phenol, and of the nitrous acid present, on the nitrosophenol, which would occur on distilling off the ether, concentrated sodium hydrate solution is added. The mass of sodium nitrosophenol which separates is spread upon porous plates; when dry it is dissolved in water, the nitrosophenol is separated by sulphuric acid, and after being slightly washed, it is rapidly dissolved in hot water; the solution is then filtered, cooled, and extracted with ether. On distilling off the ether, pure nitrosophenol remains.

Nitrosophenol crystallises, on slow evaporation of an ethereal solution, in large brown rhombic plates which have their brachydiagonal axis a , macrodiagonal b , and vertical axis c in the ratio $a : b : c = 0.59264 : 1 : 2.4691$; and the angle $\angle P = 118^\circ 41' 40''$, and $P : P = 120^\circ 5' 40''$. It is moderately soluble in water, melts when heated, and at 120° – 130° decomposes with a slight explosion. Nitrosophenol is readily soluble in a dilute solution of sodium hydrate; on adding a concentrated sodium hydrate solution, sodium-nitrosophenol separates in reddish-brown needles. On oxidation by nitric acid, or by an alkaline solution of potassium ferricyanide, it is converted into paranitrophenol (m. p. 114°). By reduction with tin and hydrochloric acid it is converted into para-amidophenol. When nitrosophenol is dissolved in phenol, and a small quantity of concentrated sulphuric acid is added, the mass assumes a fine dark cherry-red colour, which changes to blue on the addition of water and solution of potassium hydrate. According to Liebermann (*ibid.* vii. 1099) the blue colouring matter thus produced has the composition $\text{C}_{12}\text{H}_{10}\text{NO}$, being formed by the action of 2 mols. of phenol on 1 mol. of nitrosophenol. To prepare it he mixes 5 grams of

phenol with an equal volume of concentrated sulphuric acid, carefully cooling to prevent, as far as possible, the formation of sulpho-acids; 20 grams of a 5 p.c. solution of potassium nitrite in concentrated sulphuric acid is then added in quantities sufficient to maintain the temperature at 40°–50° during the time that the reaction is taking place (about fifteen minutes). The liquid is then poured into a large quantity of cold water, the precipitate filtered off, drained on a porcelain plate, and dried over sulphuric acid. The substance thus obtained may be dried at 130°. It is a brown powder, easily soluble in alcohol; alkalis dissolve it, forming a blue solution.

The resin which is formed on acting upon phenol with dilute nitric acid is probably a product of the action of phenol on nitrosophenol (Baeyer a. Caro).

Chloronitrophenols. *Parachlorororthonitrophenol*, $C^6H^4Cl(NO^2)OH$ (1 : 2 : 4), is the sole product of the action of dilute nitric acid on parachlorophenol (Faust, *Deut. Chem. Ges. Ber.* vi. 132; Beilstein a. Kurbatow, *ibid.* 1396); it is also formed, probably together with orthochlorororthonitrophenol, by the action of chlorine on orthonitrophenol (Faust a. Saame, *Ann. Ch. Pharm., Suppl.* vii. 195; Armstrong a. Prevost, *Deut. Chem. Ges. Ber.* vii. 922). It melts at 86°–87°. The properties and metallic derivatives of this phenol have already been described (1st *Suppl.* 912). It is converted by chlorine into dichlorororthonitrophenol melting at 121°–122°, and by nitric acid into Dubois' parachlorodinitrophenol melting at 81° (Faust a. Saame). The barium derivative crystallises with $4H^2O$ and not with $2H^2O$, as previously stated (Faust, *Ann. Ch. Pharm.* clxxiii. 317).

Orthochloroparanitrophenol, $C^6H^3Cl(NO^2)OH$ (1 : 2 : 4), is formed on chlorinating paranitrophenol (Armstrong, *Chem. Soc. J.* 1872, 12; Faust a. Müller, *Ann. Ch. Pharm.* clxxiii. 309); together with orthochlorororthonitrophenol, on treating orthochlorophenol (b. p. 176°) with dilute nitric acid (Faust a. Müller), and by Griess's method from the chloronitroamidophenol obtained on reducing chloro- α -dinitrophenol (m. p. 110°–111°) with ammonium sulphide (Faust, *Zeitschr. f. Chem.* 1871, 339).

Orthochloroparanitrophenol is slightly soluble in cold water and moderately soluble in boiling water, from which it separates partly as an oil which rapidly solidifies, partly in white silky needles; it is very soluble in ether, chloroform, and alcohol. It melts at 110°–111°, but at a much lower temperature under water. It is only volatile to a very slight extent in a current of steam. Nitric acid (sp. gr. 1.36) readily converts orthochloroparanitrophenol into chloro- α -dinitrophenol (m. p. 110°–111°); with chlorine it furnishes dichloroparanitrophenol (m. p. 125°). The *potassium derivative*, $C^6H^3Cl(NO^2)OK + H^2O$, forms tufts of brown-yellow needles very soluble in water; the *sodium derivative* forms yellow needles very soluble in water; the *calcium derivative*, $(C^6H^3Cl(NO^2)O)^2Ca + 4H^2O$, crystallises in tufts of canary-yellow needles, easily soluble in water; the *barium derivative*, $(C^6H^3Cl(NO^2)O)^2Ba + 7H^2O$, separates from hot water, in which it is very soluble, in long dark-yellow glistening needles; the *magnesium derivative* forms pale-yellow, very soluble needles, which contain a very large amount of water of crystallisation; the *silver derivative* crystallises from hot water in tufts of copper-brown, flattened needles, difficultly soluble in water.

Orthochloroparamidophenol hydrochloride is obtained on reducing orthochloroparanitrophenol with tin and hydrochloric acid. It crystallises from water, in which it is easily soluble, in white needles (Faust a. Müller).

Orthochlorororthonitrophenol, $C^6H^4Cl(NO^2)OH$ (1 : 2 : 6), is formed, together with orthochloroparanitrophenol, when orthochlorophenol is added to nitric acid (sp. gr. 1.36) diluted with an equal weight of water (Faust a. Müller, *loc. cit.*). At first a red oil is produced, but after a time this becomes solid; it is allowed to remain for 24 hours in contact with the acid, then removed, washed, and boiled with barium carbonate. The difficultly soluble barium orthochlorororthonitrophenol is readily separated from the easily soluble barium orthochloroparanitrophenol by crystallisation.

Orthochlorororthonitrophenol is but slightly soluble in water; it dissolves easily in chloroform, from which it crystallises in flat yellow imperfectly developed needles. It volatilises readily in a current of steam, and may therefore be separated from orthochlorororthonitrophenol by distillation with water. It melts at 70°. Nitric acid converts it into chloro- α -dinitrophenol (m. p. 110°–111°). The *potassium derivative* crystallises in long dark-red glistening flat needles, easily soluble in water; the *calcium derivative*, $(C^6H^3Cl(NO^2)O)^2Ca + H^2O$, forms short red-brown prisms, which are often grouped in wart-like forms, and are somewhat difficultly soluble in water; the *barium derivative*, $(C^6H^3Cl(NO^2)O)^2Ba + H^2O$, forms short copper-brown plates, which are usually united in little warts; it is scarcely more soluble in hot than in cold water, very little separating from the hot saturated solution as it cools. The *silver derivative*, $C^6H^3Cl(NO^2)OAg$, forms carmine-red glistening scales, difficultly soluble in water.

Dichloroparanitrophenol or *Diorthochloroparanitrophenol*, $C^6H^2Cl_2(NO^2)OH$ (1 : 2 : 4 : 6).—The preparation of this compound (m. p. 125°), which was first obtained by

Seifart by chlorination of paranitrophenol (m. p. 114°), has previously been described (1st Suppl. 913); in this case orthochloroparanitrophenol (m. p. 110° - 111°) is first produced. It is also formed on carefully treating dichlorophenolsulphonic acid, prepared from phenolparasulphonic acid, with nitric acid (Armstrong, *Chem. Soc. J.* 1871, 1112; Faust, *Zeitschr. f. Chem.* 1871, 338). Seifart states that the barium derivative crystallises in brown-red prisms or light-red needles, according to concentration (1st Suppl. 913). According to Faust a. Müller, it forms either red flat needles with $4\text{H}_2\text{O}$ or long yellow needles with $8\text{H}_2\text{O}$; the former separates first, the latter only appearing after some hours; both modifications yield both forms in the same order on recrystallisation (*Ann. Ch. Pharm.* clxxiii. 311). By the action of dilute nitric acid dichloroparanitrophenol may be converted into chloro- α -dinitrophenol (Armstrong, *loc. cit.*) When it is heated above its melting point it is decomposed with evolution of nitrogen, nitric oxide, and nitric peroxide; a sublimate consisting of long yellow needles of dichloroquinone and white prismatic crystals of an unknown body collects in the tube, and a brown-red residue is left (Armstrong a. Brown, *Deut. Chem. Ges. Ber.* vii. 926).

A dichloronitrophenol, described by Peterson as melting at 106° (*Ann. Ch. Pharm.* clviii. 163), has since been shown by him (*Deut. Chem. Ges. Ber.* 1873, 370) to be impure dichloroparanitrophenol.

Dichlororthonitrophenol or *Parachlorororthochlororthonitrophenol*, $\text{C}^6\text{H}^3\text{Cl}^2(\text{NO}^2)\text{OH}$ (1 : 2 : 4 : 6), which is produced on nitrating the dichlorophenol melting at 42° - 43° (1st Suppl. 913), is also formed when chlorine is passed into an aqueous solution of orthonitrophenolparasulphonic acid, and by the action of nitric acid on the dichlorophenolsulphonic acid produced by acting upon dichlorophenol (m. p. 42° - 43°) with sulphuric chlorhydrate, which is doubtless identical with that formed on chlorinating Kekulé's phenolmetasulphonic acid (phenolorthosulphonic acid), (Armstrong, *Chem. Soc. J.* 1871, 1119; 1872, 93; Faust, *Zeitschr. f. Chem.* 1871, 338). The potassium derivative of this dichloronitrophenol, which is usually anhydrous, occasionally crystallises with a molecule of water (Faust, *Ann. Ch. Pharm.* clxxiii. 317).

Dichlorororthamidophenol or *Orthochloroparachlorororthamidophenol*, $\text{C}^6\text{H}^3\text{Cl}^2\text{NH}^2\text{OH}$ (1 : 2 : 4 : 6).—The hydrochloride of this compound is readily obtained by reducing dichlororthonitrophenol (m. p. 121°) with tin and hydrochloric acid; when the action is completed it is precipitated by the addition of concentrated hydrochloric acid, redissolved in a small quantity of water, reprecipitated by acid, and dried on porous plates. It is readily converted into dichlorodiazophenol, $\text{C}^6\text{H}^2\text{Cl}^2\text{ON}^2$, which is obtained uncombined with hydrochloric acid, by the action of nitrous acid either on an aqueous or on an alcoholic solution (Schmitt a. Glutz, *Deut. Chem. Ges. Ber.* ii. 52).

Orthochloro- α -dinitrophenol or *Orthochlororthonitroparanitrophenol*, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)_2\text{OH}$ (1 : 2 : 4 : 6).—This compound, which is the β -chlorodinitrophenol of Faust a. Saame, melting at 110° - 111° (1st Suppl. 914), is identical with the chlorodinitrophenol (γ -chlorodinitrophenol; *ibid.*) obtained by Griess (Armstrong, *Chem. Soc. J.* 1872, 96), and with that formed on treating trinitrophenol according to Stenhouse's method (1st Suppl. 914) with iodine chloride (Peterson, *Deut. Chem. Ges. Ber.* vi. 368). It is also produced:—1. By the action of chlorine on α -dinitrophenol (Armstrong, *Chem. Soc. J.* 1872, 12; Faust, *Zeitschr. f. Chem.* 1871, 339). 2. On nitration of orthochloroparanitrophenol (Armstrong, *loc. cit.*; Faust a. Müller, *Ann. Ch. Pharm.* clxxiii. 309). 3. On nitration of orthochlororthonitrophenol (Faust a. Müller). 4. By heating diazodinitrophenol from amidodinitrophenol (picramic acid) with hydrochloric acid (Faust, *loc. cit.*) 5. By the action of nitric acid on dichlorophenolparasulphonic acid (Armstrong, *Chem. Soc. J.* 1871, 119; Faust, *loc. cit.*) 6. By the action of nitric acid on dichloroparanitrophenol (Armstrong).

The potassium derivative, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)_2\text{OK} + \text{H}_2\text{O}$, crystallises in short, fine, yellow needles; the sodium derivative, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)_2\text{ONa} + 1\frac{1}{2}\text{H}_2\text{O}$, also in short yellow needles. The ammonium derivative crystallises with $1\frac{1}{2}\text{OH}^2$, and the barium derivative with $9-10\text{OH}^2$. *Calcium chloro- α -dinitrophenol*, $[\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)_2\text{O}]^2\text{Ca} + 7\text{H}_2\text{O}$, forms long, flat, pointed, golden-yellow needles; it is one of the most beautiful and characteristic of the derivatives of this phenol. The magnesium derivative crystallises in long, capillary, pointed, pale-yellow needles, which contain $7-10\text{H}_2\text{O}$ according to concentration; the copper derivative, $[\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)_2\text{O}]^2\text{Cu} + 8\text{H}_2\text{O}$, forms long, hair-fine, branched, silky needles of greenish-yellow colour, which become dark brown on drying. All these are readily soluble in hot water, but difficultly soluble in cold water.

Orthochlorororthamidoparanitrophenol, $\text{C}^6\text{H}^3\text{Cl}(\text{NH}^2)(\text{NO}^2)\text{OH}$ (1 : 2 : 4 : 6), is obtained on reducing chloro- α -dinitrophenol by ammonium sulphide (Faust, *Zeitschrift f. Chem.* 1871, 339; *Ann. Ch. Pharm.* clxxiii. 316; Armstrong, *Chem. Soc. J.* 1872, 14). It separates from hot water, in which it is moderately soluble, in long, fine, brass-yellow
2nd Sup.

needles of the composition, $C^6H^3Cl(NH^2)NO^2OH + \frac{1}{2}H^2O$. The dry substance melts at about 140° . The *barium derivative*, $[C^6H^3Cl(NH^2)(NO^2O)]^2Ba + 4H^2O$, crystallises in fine, black needles; the *sulphate*, $[C^6H^3Cl(NH^2)(NO^2O)]^2H^2SO^4$, separates from the saturated solution in yellowish, glistening plates, rather soluble in water; the *hydrochloride*, $C^6H^3ClNH^2NO^2OH.HCl$, crystallises in short, yellow needles, and is easily soluble in water.

Parachloro- β -dinitrophenol or *Parachlorodiorthonitrophenol*, $C^6H^2Cl(NO^2)^2OH$ (1 : 2 : 4 : 6). This modification, which melts at 80° – 81° , is commonly known as Dubois chlorodinitrophenol. It is produced:—1. By nitration of parachlorophenol (Dubois). 2. By the action of nitric acid on parachlorophenolsulphonic acid (Petersen a. Baehr-Predari, *Ann. Ch. Pharm.* clvii. 156). 3. On nitration of parachlororthonitrophenol melting at 86° – 87° (Faust a. Suame). 4. By the action of sodium hydrate solution on the α -dinitroparadiachlorobenzene (m. p. 104°) of Jungfleisch (Engelhardt a. Latschinoff, *Zeitschr. f. Chem.* 1870, 234; Körner, *Gaz. chim. ital.* 1874, 395). 5. On chlorination of β -dinitrophenol (Armstrong, *Deut. Chem. Ges. Ber.* 1873, 649; Körner *loc. cit.*) 6. In small quantity together with chloro- α -dinitrophenol by the action of iodine chloride on trinitrophenol (Petersen, *Deut. Chem. Ges. Ber.* 1873, 369; Armstrong, *ibid.* 650).

Parachloro- β -dinitrophenol crystallises in monoclinic prisms which exhibit the combinations OP.—P. + $P\infty$. $\infty P\infty$; the cleavage being according to $\infty P\infty$. The orthodiagonal axis (a), the klinodiagonal (b), and the principal axis (c) are in the ratio $a : b : c = 0.59553 : 1 : 0.73070$, and the angles $\infty P : \infty P = 64^\circ 34'$; $OP : P\infty = 137^\circ 40'$; $OP : \infty P\infty = 109^\circ 30'$; $OP : \infty P = 100^\circ 17'$; $OP : -P = 132^\circ 0'$ (Hessenberg, *Ann. Ch. Pharm.* clvii. 158).

The *potassium derivative*, $C^6H^2Cl(NO^2)^2OK$, crystallises in long, fine needles of a magnificent red colour, which exhibit a metallic-green lustre; it is readily soluble in hot, but very difficultly soluble in cold water. The *ammonium derivative*, $C^6H^2Cl(NO^2)^2ONH^4$, forms fine, deep orange needles; the *sodium derivative*, $C^6H^2Cl(NO^2)^2ONa + 3H^2O$, separates in scarlet-red moss-like forms, difficultly soluble in cold water; from alcohol it crystallises in small red needles. The *barium derivative*, $[C^6H^2Cl(NO^2)^2O]^2Ba + H^2O$, crystallises in fine, glistening, pale saffron-yellow needles, very difficultly soluble even in hot water; the *lead derivative*, $[C^6H^2Cl(NO^2)^2O]^2Pb + H^2O$, is also very difficultly soluble in hot water, from which it separates in fine, glistening, yellow needles. The *copper derivative*, $[C^6H^2Cl(NO^2)^2O]^2Cu + 2H^2O$, forms saffron-yellow needles. The *silver derivative*, $C^6H^2Cl(NO^2)^2OAg$, which is very difficultly soluble in water, separates from the hot solution in fine, brilliant-red needles.

Parachloro- β -dinitrophenol, $C^6H^2Cl(NO^2)^2OC^2H^3$, crystallises from alcohol in almost colourless, glistening needles, or pale yellow rhombic plates. It melts at 54° – 55° (Petersen a. Baehr-Predari).

Other Chlorodinitrophenols.—By heating *s*-dinitroparadiachlorobenzene (m. p. 101°) with sodium hydrate solution, Engelhardt a. Latschinoff (*Zeit. f. Chem.* 1870, 234) obtained the sodium derivative of a *dinitroparachlorophenol* melting at 70° , isomeric with parachloro- β -dinitrophenol. This observation has recently been confirmed by Körner (*Gaz. chim. ital.* 1874, 395). According to the latter, the potassium derivative of this phenol crystallises in small plates of the same colour as the silver derivative of Dubois' chlorodinitrophenol.

A *metachlorodinitrophenol* has been obtained by Körner (*loc. cit.* 375, 400) by treating the dinitrometadiachlorobenzene (m. p. 103°), formed on nitrating metadiachlorobenzene (1 : 3) with potassium hydrate. The potassium derivative which is thus produced is yellow, and only slightly soluble in water.

Petersen a. Baehr-Predari (*Ann. Ch. Pharm.* clvii. 161) obtained a small quantity of a *dinitrochlorophenol*, melting at 114° , together with Dubois' chlorodinitrophenol, on nitrating the sulpho-acid from chlorophenol (b. p. 218°). Whether, if a pure substance, this was derived from the parachlorophenol, or, which appears to be more probable, from metachlorophenol present in the parachlorophenol employed, was not determined. The metallic derivatives of this compound are more soluble than, and not so well crystallised as, those of parachloro- β -dinitrophenol. The *potassium derivative*, $C^6H^2Cl(NO^2)^2OK + H^2O$, crystallises in brick-red, moss-like aggregates; when dry it has a brilliant carmine-red colour. The *ammonium derivative*, $C^6H^2Cl(NO^2)^2ONH^4 + H^2O$, forms orange-yellow needles; the *barium derivative*, $[C^6H^2Cl(NO^2)^2O]^2Ba + 2H^2O$, crystallises in ochre-yellow needles, which become orange-red on drying; the *silver derivative* separates from hot water in small, granular, pale-red crystals.

The *dinitrochlorophenol* melting at 69° which Petersen (*loc. cit.* 165) described as isomeric with Dubois' chlorodinitrophenol, he has since stated (*Deut. Chem. Ges. Ber.* vi. 369) is identical with the latter.

Bromonitrophenols. *Parabromonitrophenol*, $C^6H^4Br(NO^2)OH$ (1 : 2 : 4), is the first product of the action of nitric acid on parabromophenol (Huebner a. Brenken, *Deut. Chem. Ges. Ber.* vi. 170; Körner, *Gaz. chim. ital.*, 1874, 388; Armstrong). It melts at 87°-88°. The sodium derivative, $C^6H^4Br(NO^2)ONa$, crystallises in small deep-red needles, which exhibit a golden-green lustre, it is extremely soluble in water.

Orthobromoparanitrophenol, $C^6H^4Br(NO^2)OH$ (1 : 2 : 4), is produced when bromine acts upon paranitrophenol. It melts at 102° (1st Suppl. 912). The barium derivative, $[C^6H^4Br(NO^2)O]^2Ba + 6H^2O$, crystallises in tufts of orange-yellow needles, somewhat difficultly soluble in water (Brunck, *Zeitschr. f. Chem.* 1867, 204).

Orthobromonitrophenol, $C^6H^4Br(NO^2)OH$ (1 : 2 : 6), is apparently formed, together with parabromonitrophenol, by the action of bromine on orthonitrophenol (Armstrong a. Prevost, *Deut. Chem. Ges. Ber.* vii. 922), but it has not yet been separated in the pure state.

Dibromoparanitrophenol or *Diorthobromoparanitrophenol*, $C^6H^2Br^2(NO^2)OH$ (1 : 2 : 4 : 6), which is the end-product of the action of bromine on paranitrophenol (1st Suppl. 912), is also formed by nitration of dibromophenolparasulphonic acid (Armstrong a. Brown, *Chem. Soc. J.* 1872, 857). When heated slightly above its melting point (141°), it is decomposed; nitrogen, nitric oxide, and nitric peroxide are evolved, and a sublimate of dibromoquinone mixed with a second body is obtained in the tube in which the decomposition is effected, and a brown residue remains (Armstrong).

Dibromoparanitranisol, $C^6H^2Br^2(NO^2)OCH^3$, crystallises in white prisms melting at 122·6°; it is slightly soluble in cold alcohol, but more soluble in hot alcohol. When digested with alcoholic ammonia at 180°, it is converted into dibromoparanitroaniline, melting at 202·5°, which, on treatment with ethyl nitrite, furnishes nitrometadibromobenzene, melting at 104·5 (Körner, *Gaz. chim. ital.*, 1874, 390).

Dibromonitrophenol or *Parabromonitrophenol*, $C^6H^4Br^2(NO^2)OH$ (1 : 2 : 4 : 6).—This is formed by the action of bromine in excess on orthonitrophenol. It is also produced by nitration of ordinary dibromophenol (1st Suppl. 912), by nitration of dibromophenolorthosulphonic acid (Armstrong a. Brown, *loc. cit.* 863), and by the action of bromine on orthonitrophenolparasulphonic acid (*ibid.* 870). It melts at 117°-118°. The voluminous brown-red precipitate of the silver derivative which forms on adding silver nitrate to a dilute boiling solution of the potassium derivative, is converted, on standing 24 hours, into red needles 5-6 mm. long, which exhibit a brilliant metallic lustre; in the dry state these crystals resemble rapidly crystallised potassium chrysammate (Körner).

Dibromonitranisol, $C^6H^2Br^2(NO^2)OCH^3$, which is produced on digesting the silver derivative with methyl iodide, crystallises in long needles which exhibit a slight yellowish-green tinge; it melts at 76·7°. It is converted by alcoholic ammonia at 170° into dibromonitroaniline (m. p. 127·3°), which, on treatment with ethyl nitrite, furnishes the same nitrometadibromobenzene (m. p. 104·5°) that is obtained from dibromoparanitrophenol by a similar series of reactions (Körner, *loc. cit.* 392).

Orthobromo- α -dinitrophenol or *Orthobromonitroparanitrophenol*, $C^6H^4Br(NO^2)_2OH$ (1 : 2 : 4 : 6), was first obtained by Laurent (*Rev. Scient.* vi. 65) by the action of bromine on α -dinitrophenol. It is also produced: 1. On nitration of orthobromoparanitrophenol (Körner, *loc. cit.* 394; Armstrong). 2. On nitration of orthobromophenol (Körner; Armstrong). 3. Together with parabromo- β -dinitrophenol on nitrating the product of the action of 1 mol. of bromine on orthonitrophenol, being formed doubtless from the orthobromonitrophenol present in the mixture (Armstrong a. Prevost). 4. On nitration of dibromophenolparasulphonic acid (Armstrong a. Brown, *Chem. Soc. J.* 1872, 861). 5. On nitration of bromophenoldisulphonic acid (Armstrong, *ibid.* 865). 6. By digesting trinitrophenol with bromine iodide and water (Armstrong, *Deut. Chem. Ges. Ber.* vi. 650). 7. By the action of potassium hydrate solution on the bromodinitroaniline (m. p. 144°) obtained on treating ordinary dinitroaniline (1 : 2 : 4) with bromine (Körner, *loc. cit.* 394).

Orthobromo- α -dinitrophenol melts at 118·2° (Körner). It separates from boiling water, in which, however, it is only slightly soluble, in short, fine, almost colourless needles. It is readily soluble in hot alcohol, from which it crystallises in long hair-fine needles. The potassium derivative, $C^6H^4Br(NO^2)_2OK + H^2O$, forms brilliant yellow flat needles; it also separates in orange prismatic needles containing 1 mol. of water, and the salt with $1\frac{1}{2}$ mol. of water readily parts with the $\frac{1}{2}$ mol. on exposure to the air. Both forms are difficultly soluble in cold water, although readily dissolved by hot water. The barium derivative, $[C^6H^4Br(NO^2)_2O]^2Ba + 4-6H^2O$, is very difficultly soluble in water; it crystallises in short needles of a more or less deep yellow colour, according to the state of concentration and temperature of the solution from which it separates; the darker forms always contain more water of crystallisation.

tion than the lighter. The *calcium derivative*, $[\text{C}^6\text{H}^3\text{Br}(\text{NO}_2)_2\text{O}]^+\text{Ca} + 7 - 8\text{H}_2\text{O}$, is readily soluble in hot water, but difficultly in cold; it separates from a hot concentrated solution in brilliant orange-red rhombic plates, and from very dilute solutions in short fine yellow needles (Armstrong a. Brown). According to Huebner a. Brecken the yellow salt contains 12OH^2 . The orange-red form is gradually converted into the yellow if it be allowed to remain in the solution.

The bromodinitroaniline (m. p. 144°) from which this bromodinitrophenol may be obtained (*supra*) is not attacked by ethyl nitrite (Körner).

Parabromo- β -dinitrophenol or *Parabromodithionitrophenol*, $\text{C}^6\text{H}^3\text{Br}(\text{NO}_2)_2\text{OH}$ (1 : 2 : 4 : 6).—This compound, first obtained by Körner on nitration of crude bromophenol (*Ann. Ch. Pharm.* cxxxvii. 205), is formed: 1. By the action of nitric acid on parabromophenol (Körner, *Gaz. chim. ital.*, 1874, 388; Armstrong). 2. By the action of nitric acid on pure parabromorthonitrophenol (Armstrong), so that it is produced, together with orthobromo- α -dinitrophenol, on nitrating the mixture of parabrom- and orthobrom-orthonitrophenol formed by the action of 1 mol. of bromine on orthonitrophenol (Armstrong a. Prevost, *Deut. Chem. Ges. Ber.* vii. 922). 3. By the action of bromine on β -dinitrophenol (Körner, *loc. cit.* 327, 397; Armstrong). It is very difficultly soluble even in boiling water, and separates on cooling in short yellow needles. From ether, in which it dissolves easily, it crystallises in large orange prisms. It melts at 75.6° (Körner). When heated with water and bromine on the water-bath, bromo- β -dinitrophenol is converted into bromo- α -dinitrophenol; hence it is necessary, in the preparation of bromo- β -dinitrophenol from β -dinitrophenol and bromine, to warm the mixture gently to 50° – 60° (Armstrong). The *potassium derivative*, $\text{C}^6\text{H}^3\text{Br}(\text{NO}_2)_2\text{OK}$, which is very difficultly soluble in cold water, and far less soluble in boiling water than potassium orthobromo- α -dinitrophenol, crystallises in magnificent flat crimson needles, which exhibit a beautiful metallic-green lustre, especially when viewed surrounded by water. The *silver derivative* resembles most closely that of the corresponding (Dubois') chlorodinitrophenol, but has a slightly deeper colour.

Other Bromodinitrophenols. Metabromodinitrophenol, $\text{C}^6\text{H}^3\text{Br}(\text{NO}_2)_2\text{OH}$.—The potassium derivative of this compound is obtained on heating the dinitrometadibromobenzene (m. p. 117.4°), which is produced by the action of a mixture of nitric and sulphuric acids on nitrometadibromobenzene (1 : 3 : 4) melting at 61.6° , with an aqueous solution of 2 mols. of potassium hydrate. It is also formed on nitration of metabromophenol (1 : 3; Körner, *loc. cit.* 389, 398). It is easily soluble in alcohol and ether, from which it crystallises in large transparent, almost colourless prisms; it is precipitated from a concentrated cold aqueous solution by hydrochloric acid in small plates, and from a hot, less concentrated, solution in long needles. It is soluble in concentrated nitric acid, but precipitated in plates on the addition of water. It melts at 91.5° . The *potassium derivative* is dimorphous. If crystallised from the nearly boiling solution, it separates in long bright yellow anhydrous needles, which present a magnificent setaceous appearance; and these, if left in the solution, suddenly assume a paler colour; also if the darker salt be heated to 120° the crystals fall to a powder consisting of minute crystals of the lighter salt. When crystallised at a very low temperature, the potassium derivative forms large transparent bright-yellow rhombic plates which contain water of crystallisation; these very readily part with their water, even when immersed in the solution, and become opaque. The *calcium* and *barium derivatives* are obtained on the addition of calcium or barium chloride to a hot solution of the potassium derivative, in long yellow pointed needles. They detonate more violently than potassium trinitrophenol when heated. The *silver derivative* is thrown down as a bulky yellow precipitate on the addition of silver nitrate to a solution of the potassium derivative; when touched with a glass rod it assumes a magnificent red colour at the point of contact, which soon extends to the whole mass. When it is dissolved in a large quantity of boiling water, and the solution is cooled, it separates in small needles and laminae, perfectly united in strawberry-like forms, of a magnificent dark crimson-red colour, which rival velvet in softness and splendour. *Metabromodinitranisole*, $\text{C}^6\text{H}^3\text{Br}(\text{NO}_2)_2\text{OCH}_3$, crystallises from ether in small prisms, from alcohol in rhombic plates of a greenish-yellow colour; it melts at 109.4° (Körner).

Iodonitrophenols. Orthiodoparanitrophenol, $\text{C}^6\text{H}^3\text{I}(\text{NO}_2)_2\text{OH}$ (1 : 2 : 4), which melts at 93° – 94° , has already been described (1st Suppl. 914). Busch's statement (*Deut. Chem. Ges. Ber.* vii. 462) that the iodonitrophenol obtained by the action of iodine and mercuric oxide on non-volatile nitrophenol does not possess the properties ascribed to it by Körner, and that it melts at 154° – 155° , is incorrect; the substance he obtained was undoubtedly diiodoparanitrophenol (Armstrong). Orthiodoparanitrophenol is readily converted into iodo- α -dinitrophenol (m. p. 106°) by the action of nitric acid (Armstrong).

Iodorthonitrophenols, $C^6H^4I(NO^2)OH$.—According to Busch the action of iodine and mercuric oxide on orthiodonitrophenol (volatile nitrophenol) dissolved in glacial acetic acid, gives rise to the formation of two isomeric iodonitrophenols, viz: α -iodonitrophenol, which melts at 90° – 91° , crystallising in long yellow needles, easily soluble in hot water, alcohol, and ether; and β -iodonitrophenol, which melts at 66° – 67° , and crystallises in short yellow needles easily soluble in hot water, alcohol, and ether. The α -compound is difficultly volatile in a current of steam; the β -compound, however, volatilises readily. Potassium- α -iodonitrophenol, $C^6H^3I(NO^2)OK$, forms red needles very easily soluble in water, but difficultly soluble in alcohol; the β -derivative, $C^6H^3I(NO^2)OK + H^2O$, crystallises in small golden-red glistening plates, very easily soluble in water and alcohol. Busch's description of the iodonitrophenols from orthonitrophenol appears to be very incorrect (Armstrong). When the product of the action of iodine and mercuric oxide is submitted to distillation in a current of steam, orthonitrophenol, together with a certain quantity of iodorthonitrophenol, passes over; the residue consists of iodo- and diiodo-orthonitrophenol. If the volatilised portion be dissolved in potassium carbonate solution, the potassium derivative of an iodonitrophenol separates in crystals, such as, according to Busch, are formed by potassium β -iodonitrophenol; but the phenol from these, after repeated recrystallisation from alcohol, melts at 109° – 110° , and furnishes a potassium derivative, $C^6H^3I(NO^2)OK + H^2O$, crystallising in aggregates of somewhat irregularly developed rhombic plates of a magnificent garnet-red colour by transmitted light; in reflected light these crystals exhibit a beautiful golden-green metallic lustre; they are easily soluble in hot, but difficultly soluble in cold water and alcohol. When the mixture of iodo- and diiodonitrophenol above referred to is treated with potassium carbonate solution, the solution evaporated to dryness, and the mixture of dry salts extracted with boiling alcohol, a considerable quantity of the potassium derivative of the phenol melting at 109° – 110° is likewise obtained; this iodorthonitrophenol crystallises in orange prisms or needles; it is readily soluble in boiling alcohol, but difficultly soluble in cold alcohol; it is only very slightly soluble in water, and does not volatilise to any considerable extent in a current of steam. Busch's α -iodonitrophenol was probably impure diiodonitrophenol (m. p. 98°).

Orthiodo- α -dinitrophenol or **Orthiodorthonitroparanitrophenol**, $C^6H^2I(NO^2)_2OH$ (1 : 2 : 4 : 6).—This compound was first obtained, but in an impure state, by the action of iodine and iodic acid on α -dinitrophenol by Körner. It is also produced: 1. By the action of iodine and mercuric oxide on α -dinitrophenol (Armstrong, *Deut. Chem. Ges. Ber.* vi. 651; Weselsky, *Ann. Ch. Pharm.* clxxiv. 111). 2. By the action of hydriodic acid on diazodinitrophenol (Körner; Armstrong). 3. By the action of nitric acid on orthiodoparanitrophenol (Armstrong). It crystallises from boiling water, in which, however, it is only sparingly soluble, in long fine lemon-yellow needles which melt at 106° (Armstrong), 108° (Weselsky). The potassium derivative, $C^6H^2I(NO^2)_2OK$, forms deep orange coloured needles, easily soluble in hot, but difficultly in cold water. The calcium derivative, $[C^6H^2I(NO^2)_2O]Ca + 5H^2O$, crystallises in beautiful orange-red monoclinic (?) plates, easily soluble in hot water, but difficultly in cold; the barium derivative crystallises in flat needles of the colour of potassium dichromate.

Paraiodo- β -dinitrophenol or **Paraiododithonitrophenol**, $C^6H^2I(NO^2)_2OH$ (1 : 2 : 4 : 6), is produced by the action of iodine and mercuric oxide on an alcoholic solution of β -dinitrophenol (Armstrong, *Deut. Chem. Ges. Ber.* vi. 649). The potassium derivative is obtained when iodine and iodic acid are added to a solution of β -dinitrophenol in a large excess of potassium hydrate solution, and the liquid alternately rendered acid and alkaline (Körner, *Gaz. chim. ital.*, 1874, 397). It crystallises from water, in which it is very sparingly soluble, in short fine yellow needles, melting at 113° . The potassium derivative forms magnificent carmine-red needles, which, however, when viewed in certain directions, exhibit the splendid metallic-green appearance of mercuric oxide, and in others a golden-yellow colour; it is very difficultly soluble in water. The silver derivative is precipitated by silver nitrate from a dilute boiling solution of the potassium derivative in magnificent brown-red small needles.

Sulpho-phenols or Phenolsulphonic Acids. The experiments of Faust (*Zeitschr. f. Chem.* 1871, 339), of Armstrong, and of Armstrong & Brown (*Chem. Soc. J.* 1871, 1112; 1872, 12, 857), do not lend support to Solomonoff's statement (1st Suppl. 924) that the action of sulphuric acid on phenol produces simultaneously three isomeric phenolmonosulphonic acids, $C^6H^4OH.SO^3H$, but confirm Kekulé's view that only two are formed.

Phenolorithosulphonic acid. Kekulé's Phenolmetasulphonic acid (β -Phenylsulphuric acid; 1st Suppl. 923). $C^6H^3OH.SO^3H$ (1 : 2). Solomonoff's experiments (*Zeitschr. f. Chem.* 1869, v. 296) on the action of benzoyl

chloride on potassium phenolorthosulphonate do not in the least confirm Engelhardt a. Latschinoff's view that the α - and β -acids formed from phenol and sulphuric acid are related in the same manner as isethionic acid and hydrogen ethyl-sulphate, but are quite in accordance with the view that both are oxybenzenesulphonic acids, since by heating the potassium salt of the β -acid with benzoyl chloride, he obtained *benzophenid*, $C^6H^4(OH).CO.O^2H^3$, and not benzophenone, $C^6H^4.CO.O^2H^3$ (1st Suppl. 926); the precise nature of the reaction which takes place cannot, however, be stated, as the composition of the product containing sulphur has not been ascertained.

When heated with water and hydrochloric or sulphuric acid in sealed tubes at about 140° , phenolorthosulphonic acid yields phenol and sulphuric acid (Armstrong).

Aniline-phenolorthosulphonate, $C^6H^4(OH).SO^2(NH^2.C^6H^5)$, is resolved into phenol and sulphanilic acid when carefully distilled (Kopp, *Deut. Chem. Ges. Ber.* iv. 978): $C^6H^4(OH).SO^2(NH^2.C^6H^5) = C^6H^5.OH + C^6H^5.NH^2.SO^2H$. By the action of nitric acid on potassium phenolorthosulphonate, the potassium salt of a nitrophenolorthosulphonic acid is produced, which does not appear to be identical with that formed from paranitrophenol and sulphuric acid (Post, *ibid.* vii. 1323).

Phenolparasulphonic acid, $C^6H^4.OH.SO^2H$ (1 : 4).—According to Kekulé, potassium phenolparasulphonate yields resorcin when fused with an excess of potassium hydrate, although always in small quantity. Lincke (*J. pr. Chem.* [2], viii. 43) has made a series of experiments on this subject, and also finds that very little resorcin is produced, but at temperatures above 300° a reaction occurs which results in the formation of a diphenol, $C^{12}H^{10}(OH)^2$, isomeric with that obtained by Barth on fusing phenol with potassium hydrate, but identical with the diphenol which Griess procured by heating tetrazodiphenyl nitrate with water (iv. 412).

Aniline-phenolparasulphonate melts at about 170° and decomposes at 180° – 190° , pure phenol distilling over, and a residue of sulphanilic acid being left (Kopp). Phenolparasulphonic acid is decomposed into phenol and sulphuric acid on heating with water and sulphuric or hydrochloric acid in sealed tubes at about 150° ; it is, however, far less readily decomposed than the isomeric acid (Armstrong).

When potassium phenolparasulphonate is heated for some time with double the weight of phosphorus pentachloride in a flask or retort connected with a reversed condenser, and then distilled, a product is obtained which, on rectification, yields a mixture of sulphurous chloride, $SOCl^2$, and phosphoric chloride, $POCl^3$, boiling at 60° – 120° ; from the higher portions of the distillate an oil boiling at 265° – 267° may be separated by rectification, and, when the intermediate portions are added to water, a considerable quantity of paradi-chlorobenzene is obtained, together with a solution containing hydrochloric, phosphoric, and monochlorophenolphosphoric acids. The dichlorobenzene boils at 173° – 174° , and melts at 53° – 54° . The oil boiling at about 265° has the composition $C^6H^4Cl^2PO^2 = POCl^2(OC^6H^4Cl)$; it is converted by water into chlorophenylphosphoric acid, $PO(OH)^2(OC^6H^4Cl)$, and by heating with phosphorus pentachloride into dichlorobenzene. When heated with water in sealed tubes, chlorophenylphosphoric acid is readily converted into parachlorophenol (b. p. 217°) and phosphoric acid. The first action of the pentachloride appears to consist in the formation of phenolparasulphonic chloride, which then furnishes chlorophenol; thus:

The chlorophenol is probably in part at once converted into dichlorobenzene:

but is mainly converted by the action of the phosphoric chloride into chlorophenylphosphoric chloride:

which doubtless in part also undergoes conversion into dichlorobenzene (Barbaglia a. Kekulé, *Deut. Chem. Ges. Ber.* v. 875; vi. 943).

Phenoldisulphonic acid. Phenolorthoparadisulphonic acid, $C^6H^4.OH.(SO^2H)^2$ (1 : 2 : 4).—This compound (1st Suppl. 926) is produced when diazobenzenesulphonic acid from sulphanilic acid is warmed with fuming sulphuric acid (Armstrong a. Prevost, *Deut. Chem. Ges. Ber.* vi. 664).

Phenoltrisulphonic acid, $C^6H^3.OH.(SO^2H)^3$ (Senhofer, *Ann. Ch. Pharm.* clix. 110; Annenheim, *ibid.* clix. 28).—To prepare this acid, 16 grams of phosphoric anhydride and 30 grams of concentrated sulphuric acid are introduced into a strong glass tube and mixed to a thin paste with the aid of a glass rod; 6 grams of phenol is then added, care being taken to mix the liquids as little as possible; the tube sealed;

the contents carefully mixed; and the tube heated for several hours at 180°. The product is boiled with a large quantity of water until the smell of sulphurous anhydride is no longer apparent, an excess of milk of lime is added, and the precipitate separated by filtration; the residue is once or twice boiled with water, and the liquid added to the first filtrate. The filtrate is then treated, first with hydrogen-potassium carbonate, in order to remove the dissolved calcium hydrate, and afterwards with dipotassium carbonate until the whole of the calcium is precipitated as carbonate; a solution containing basic and normal potassium phenoltrisulphonate is thus obtained, from which the former is separated by crystallisation. When, on further evaporation, a pasty mass only is obtained, the whole is acidulated with acetic acid and evaporated to dryness; the potassium acetate is then extracted by alcohol; and the residue of tripotassium phenoltrisulphonate purified by several recrystallisations from water. To obtain the free acid, a solution of either of the potassium salts is precipitated with basic lead acetate, the precipitate is suspended in water at 100°, and decomposed by hydrogen sulphide; and the filtrate from the lead sulphide is evaporated on the water-bath to a syrup, from which the acid separates in fine needles (Senhofer). Annenheim obtained phenoltrisulphonic acid by heating oxybenzenesulphone (oxysulphobenzide), $(C^6H^4.OH)SO_2$, with thrice its weight of fuming sulphuric acid, at 180°–190° for 1 to 2 hours.

Phenoltrisulphonic acid crystallises in stellate groups of needles or in short thick prisms, containing water of crystallisation; it is extremely hygroscopic, and rapidly deliquesces on exposure to the air. The crystals dried at 100° contain $3\frac{1}{2}$ mols. of water. It begins to decompose, with separation of sulphuric acid, on heating at 105°. It is not affected by boiling with nitric acid, but is decomposed by bromine-water. A solution of the free acid, or of one of its soluble salts, is coloured a deep blood-red by ferric chloride. *Barium phenoltrisulphonate*, $[C^6H^4.OH.(SO_3H)]_2Ba + 4H_2O$, forms white crystalline scales, which dissolve in water with difficulty (Senhofer). Annenheim obtained a salt with 10 mols. of water, crystallising in small glistening prismatic plates. *Tripotassium phenoltrisulphonate*, $C^6H^4.OH.(SO_3K)_3 + 4H_2O$, crystallises in rhombic plates, easily soluble in water; the *tetrapotassium salt*, $C^6H^4.OK.(SO_3K)_4 + 2H_2O$, forms long flat concentrically grouped needles. The *silver salt*, $(C^6H^4.OH.(SO_3Ag))_2 + 1\frac{1}{2}H_2O$, crystallises in fine needles. The *basic lead salt*, $(C^6H^4SO_3O^1Pb)_2 \cdot 2PbH^2O + 4\frac{1}{2}H_2O$, is obtained as a heavy white crystalline powder, almost insoluble in water, on the addition of basic lead acetate to a solution of either of the potassium salts. *Sodium phenoltrisulphonate*, $C^6H^4SO_3O^1Na + 3H_2O$, forms very soluble colourless needles. *Cadmium phenoltrisulphonate*, $C^6H^4SO_3O^1Cd + 7H_2O$, crystallises in flat plates; the *copper salt* forms long fine green needles, which are very soluble; the *ammonium salt* forms crystalline scales, very soluble in water.

Phenoltetrasulphonic acid, $C^6H.OH.(SO_3H)_4$.—Annenheim (*loc. cit.*) obtained a potassium salt crystallising in small rhombic prisms, of the composition of potassium phenoltetrasulphonate, from the product of the action of 500 grams of fuming sulphuric acid on 125 grams of phenol at 190°–200°.

Chlorophenolsulphonic acids.—*a-Parachlorophenolsulphonic acid* or *Parachlorophenolorthosulphonic acid*, $C^6H^3Cl.OH.SO_3H$ (1 : 2 : 4), is prepared by heating a mixture of parachlorophenol (1 : 4) with the equivalent quantity of fuming sulphuric acid for several hours on the water-bath, &c. (Peterson a. Baehr-Predari, *Ann. Ch. Pharm.* clvii. 121; 1st Suppl. 924). It crystallises from the concentrated aqueous solution in large, colourless, glistening plates, containing 1 mol. of water; the pure acid melts at 75°–76°, and begins to decompose at about 100°. The acid and all its salts yield an intense blue-violet colour with ferric chloride. On fusing the potassium salt with an excess of potassium hydrate at 160°, a small quantity of pyrogallol, together with traces of hydroquinone, is obtained. Nitric acid readily converts the acid and its salts into parachloro-*B*-dinitrophenol, melting at 81° (Peterson a. Baehr-Predari); the formation of this compound is preceded by that of a nitrochlorosulphonic acid (Armstrong, *Deut. Chem. Ges. Ber.* vii. 404). *Potassium chlorophenolsulphonate*, $C^6H^3Cl.OH.SO_3K + 2H_2O$, forms flat, monoclinic prisms; the anhydrous salt dissolves at 20° in 9.25 pts. of water, and at 100° in 2.24 pts. On recrystallising this salt from strong alcohol, glistening quadratic plates containing 1 mol. of water are obtained; an anhydrous salt, crystallising in small needles, is obtained if absolute alcohol be employed. The *sodium salt*, $C^6H^3ClSO_3Na$, forms colourless needles, often united in groups. The *lithium salt*, $C^6H^3ClSO_3Li + H_2O$, crystallises in granular aggregates, extremely soluble in water. The *ammonium salt*, $C^6H^3ClSO_3NH_4$, forms long, glistening needles. The *barium salt*, $(C^6H^3ClSO_3)_2Ba$, crystallises in crusts or aggregates of small needles, difficultly soluble in water; on adding barium hydrate to its solution, the *dibarium salt*, $(C^6H^3ClSO_3)_2Ba + 4H_2O$, is precipitated in small glistening needles, very difficultly soluble in water. The *calcium salt*, $(C^6H^3ClSO_3)_2Ca + 2H_2O$, crystallises in easily

soluble needles; the *magnesium salt*, $(C^6H^4ClSO^3)^2Mg + 6H^2O$, in small flat plates, or pointed flat needles. The *copper salt*, $(C^6H^4ClSO^3)^2Cu + 6H^2O$, crystallises from alcohol in small, greenish-white needles, extremely soluble in water. *Potassium ethyl-parachlorophenolsulphonate*, $C^6H^4Cl.OC^2H^5.SO^3K$, forms fine, glistening needles, united in stars.

β -Parachlorophenolsulphonic acid or *Parachlorophenolmetasulphonic acid*.—The potassium β -chlorophenolsulphonate, $C^6H^4SO^3K$, crystallising in regular stellate groups of short prisms, which Petersen a. Predari obtained (1st Suppl. 924) in small quantity from the acid prepared by adding parachlorophenol to fuming sulphuric acid, and allowing the mixture to stand for some days without heating, was perhaps derived from this acid. It was not obtained when the mixture of phenol and acid was heated. It is somewhat less soluble than potassium α -parachlorophenolsulphonate; the solution is a deep-violet; nitric acid converts it into parachloro- β -dinitrophenol (m. p. 81°). On fusion with potassium hydrate, it furnishes pyrogallol in small quantity.

Orthochlorophenolsulphonic acids.—According to Kramers (*Ann. Ch. Pharm.* clxxiii. 331) the action of sulphuric acid on orthochlorophenol (1 : 2) produces two isomeric sulpho-acids, which he terms γ - and δ -chlorophenolsulphonic acid. The δ -acid is produced in relatively small quantity, together with the γ -acid, when the chlorophenol is gradually added to a carefully cooled mixture of 1 pt. of fuming with 1–2 pts. of ordinary sulphuric acid; the γ -acid alone is produced if the cooling be omitted, or if fuming sulphuric acid only is employed. To separate the two acids, the product is poured into water, and milk of lime is added to alkaline reaction; the concentrated filtrate is placed over sulphuric acid, when after some days small needles of the δ -dicalcium salt separate, and afterwards, the much more soluble dicalcium salt of the γ -acid separates from the mother-liquor in botryoidal masses.

Orthochlorophenolparasulphonic acid or *γ -Chlorophenolsulphonic acid*, $C^6H^4Cl.OH.SO^3H$ (1 : 2 : 4). This acid crystallises from the concentrated aqueous solution in small colourless plates, or from a less concentrated solution placed over sulphuric acid, in small cubes containing 1 mol. of water. It begins to decompose at 80°; with ferric chloride it yields a magnificent violet colour. *Potassium orthochlorophenolparasulphonate*, $C^6H^4ClSO^3K + \frac{1}{2}H^2O$, forms large, colourless, apparently triclinic prisms; one part of the anhydrous salt dissolves in 7.11 pts. of water at 9°. It is converted by dilute nitric acid into potassium orthochlorororthonitrophenolparasulphonate, which on further treatment with nitric acid yields chloro- α -dinitrophenol, melting at 110°–111° (Armstrong). The *dipotassium salt*, $C^6H^4ClSO^3K^2 + 3\frac{1}{2}H^2O$, crystallises in deliquescent leaf-like forms, united together. The *monosodium salt*, $C^6H^4ClSO^3Na + 11H^2O$, is so extremely soluble in water and alcohol, that it cannot be obtained in the crystallised state; the *disodium salt*, $C^6H^4ClSO^3Na^2 + 3H^2O$, separates in indistinct white crystals, extremely soluble in water, but almost insoluble in alcohol. The *monocalcium salt*, $(C^6H^4ClSO^3)^2Ca + 11H^2O$, forms small white crystals, very soluble in water and alcohol; the *dicalcium salt*, $(C^6H^4ClSO^3)^2Ca^2 + 71H^2O$, crystallises in white aggregates, which soon effloresce when exposed to the air; 1 pt. of the anhydrous salt dissolves in 2.64 pts. of water at 12°; it is almost insoluble in alcohol. The *monobarium salt*, $(C^6H^4ClSO^3)^2Ba + 1\frac{1}{2}H^2O$, separates in small white crystals united in granular aggregates. The *lead salt*, $(C^6H^4ClSO^3)^2Pb + 4H^2O$, crystallises in small, hard, rhombic crystals, soluble in water and alcohol; it is decomposed when heated above 130°, with evolution of chlorophenol; the *di-salt*, $(C^6H^4ClSO^3)^2Pb^2 + 2H^2O$, separates as a white powder difficultly soluble in cold water, and insoluble in alcohol. Basic lead salts of variable composition are also readily produced. The *copper salt*, $(C^6H^4ClSO^3)^2Cu + 4H^2O$, forms blue-green rhombic prisms, which are decomposed when heated above 120°.

δ -Chlorophenolsulphonic acid, $C^6H^4Cl.OH.SO^3H$.—The *monopotassium salt*, $C^6H^4ClSO^3K$, crystallises in small plates. The *dicalcium salt*, $(C^6H^4ClSO^3)^2Ca^2 + 4H^2O$, forms small needles; 1 pt. of the anhydrous salt dissolves in 44.68 pts. of water at 11°; it is insoluble in alcohol.

Parachlorophenoldisulphonic acid, $C^6H^4Cl.OH.(SO^3H)^2$.—An acid of this composition was obtained by Petersen a. Baehr-Predari by heating parachlorophenol with sulphuric acid, but not examined; the barium salt is very difficultly soluble in water.

Diorthochlorophenolparasulphonic acid, $C^6H^4Cl^2.OH.SO^3H$ (1 : 2 : 4 : 6), which was first prepared by Kolbe a. Gauke (1st Suppl. 924), may be produced by the action of sulphuric acid on Seifart's diorthochlorophenol (*ibid.* 908; Armstrong). The action of nitric acid on this acid and its potassium salt have been investigated at length by Faust (*Zell. f. Chem.* 1871, 338) and by Armstrong (*Chem. Soc. J.* [2], ix. 1112).

Orthochloroparachlorophenolorthosulphonic acid, $C^6H^3Cl^2.OH.SO^3H$ (1 : 2 : 4 : 6).—This compound is produced when chlorine acts upon phenolorthosulphonic acid (Faust; Armstrong), and by the action of sulphuric acid or chlorhydric sulphate on the dichlorophenol melting at $42^\circ-43^\circ$ (Armstrong, *Chem. Soc. J.* [2], x, 93). The metallic salts of this acid have not yet been examined. By the action of nitric acid it is readily converted into dichlororhthonitrophenol (m. p. 121°).

Trichlorophenolsulphonic acid.—Trichlorophenol dissolves in warm fuming sulphuric acid, and the solution solidifies on cooling to a mass of crystals (Kekulé, *Org. Chem.* iii, 233). When chlorhydric sulphate is added to trichlorophenol, hydrochloric acid is evolved; the product dissolves in great part in water, but on standing, trichlorophenol separates from the solution, in consequence, it would appear, of the gradual decomposition of the sulpho-acid (Armstrong).

Bromophenolsulphonic Acids. **Bromophenolparasulphonic acid**, $C^6H^3Br.OH.SO^3H$.—The potassium salt of this acid is formed in relatively small quantity, together with potassium dibromophenolparasulphonate, on adding 1. mol. of bromine to a cold aqueous solution of 1 mol. of potassium phenolparasulphonate (Senhofer, *Ann. Chem. Pharm.* clvi, 102). Potassium bromophenolparasulphonate crystallises in prisms; its aqueous solution is coloured a pale violet by ferric chloride, and is precipitated by basic lead acetate.

Bromophenolorthosulphonic acid.—The potassium derivative of this compound is formed in a similar manner from potassium phenolorthosulphonate (Senhofer); it crystallises in pointed needles; its solution is precipitated by lead acetate. The barium salt is moderately soluble in hot water, and crystallises in anhydrous forms; the copper salt is also anhydrous.

Diorthobromophenolparasulphonic acid, $C^6H^2Br^2.OH.SO^3H$ (1 : 2 : 4 : 6).—The potassium derivative of this acid may be obtained in theoretical quantity by the action of 2 mols. of bromine on a cold dilute aqueous solution of 1 mol. of potassium phenolparasulphonate (Senhofer, *loc. cit.*; Armstrong a. Brown, *Chem. Soc. J.* 1872, 857). The free acid crystallises in small rectangular plates; its solution is coloured pale violet by ferric chloride, and is not precipitated by normal lead acetate, although it is precipitated by basic acetate. The potassium salt, $C^6H^2Br^2.SO^3K$, crystallises in anhydrous plates, or in long needles with 1 mol. of water; it is difficultly soluble in cold water. The dipotassium salt, $C^6H^2Br^2.SO^3K^2 + 2H^2O$, crystallises from a concentrated solution in elongated plates. The sodium salt, $C^6H^2Br^2.SO^3Na + 2H^2O$, forms long, brilliant, white needles, easily soluble in hot, but difficultly soluble in cold water. The barium salt, $(C^6H^2Br^2.SO^3)^2Ba + 2H^2O$, crystallises in long, fine, silky needles, very difficultly soluble in cold water; the dibarium salt, $(C^6H^2Br^2.SO^3)^2Ba^2 + 8H^2O$, forms long needles, more soluble in water than the monobarium salt. Potassium dibromophenolparasulphonate yields potassium nitrobromophenolparasulphonate, dibromoparanitrophenol (m. p. 141°), and bromo- α -dinitrophenol (m. p. 117°), on treatment with nitric acid (Armstrong a. Brown).

The dibromophenolsulphonic acid which Schmitt (*Ann. Chem. Pharm.* cxx, 181) obtained from dibromosulphanilic acid by Griess's method is probably diorthobromophenolsulphonic acid.

Parabromorhthobromophenolorthosulphonic acid, $C^6H^2Br^2.OH.SO^3H$ (1 : 2 : 4 : 6).—Potassium dibromophenolorthosulphonate is produced, together with some tribromophenol, when bromine is added to an aqueous solution of potassium phenolorthosulphonate (Senhofer; Armstrong a. Brown). It is also formed by the action of 1 mol. of bromine on a solution of 1 mol. of potassium orthobromophenolorthoparadisulphonate (Armstrong, *Chem. Soc. J.* 1872, 867). The free acid crystallises in concentrically-grouped needles; the aqueous solution is coloured an intense violet by ferric chloride, and is precipitated by normal lead acetate. The potassium salt crystallises in fine anhydrous needles; the dipotassium salt separates from dilute alcohol in long glistening plates. The barium salt forms difficultly soluble anhydrous plates; the dibarium salt is also anhydrous. The cadmium salt, $C^6H^2Br^2.SO^3Cd + 1\frac{1}{2}H^2O$, crystallises in very soluble yellow plates. The lead salt, $C^6H^2Br^2.SO^3Pb$, separates as a white precipitate on the addition of lead acetate to a solution of the potassium salt.

Potassium dibromophenolorthosulphonate is converted by nitric acid into dibromorhthonitrophenol (m. p. 117°).

Orthobromophenolorhthoparadisulphonic acid, $C^6H^3Br.OH.(SO^3H)^2$ (1 : 2 : 4 : 6).—The potassium salt of this acid is prepared by the action of 1 mol. of bromine on a cold aqueous solution of 1 mol. of potassium phenoldisulphonate (1st Suppl, 926); it is very soluble in hot, and moderately in cold water, and crystallises in needles or tufts of short flat blades, which rapidly disintegrate to a snow-white anhydrous powder on exposure to the air. It is not precipitated, except in very con-

centrated solutions, by barium chloride. It is violently acted upon by nitric acid yielding potassium bromonitrophenolsulphonate, bromo-*o*-dinitrophenol, and trinitrophenol, in proportions which vary with the strength of the acid employed (Armstrong, *Chem. Soc. J.* 1872, 866).

Diiodophenolparasulphonic acid, $C^6H^2I^2.OH.SO^3H$, is formed by the action of iodine and mercuric oxide on an alcoholic solution of phenolparasulphonic acid (Armstrong). The *potassium salt*, $C^6H^2I^2.SO^3K + 2H^2O$, crystallises in long pink needles; the *barium salt*, $(C^6H^2I^2.SO^3)^2Ba + 4H^2O$, forms long, flat needles.

Nitrophenolsulphonic Acids. *Paranitrophenolorthosulphonic acid*, $C^6H^3.OH.NO^2.SO^3H$ (1 : 2 : 4).—Körner a. Post have obtained this acid by acting upon paranitrophenol with fuming sulphuric acid (*Deut. Chem. Ges. Ber.* v. 852, 1055; vi. 395; vii. 163; *Chem. Soc. J.* 1873, 757). The perfectly dry paranitrophenol is added to the acid and the mixture heated several hours in the water bath; if the nitrophenol be wet, and consequently much heat be evolved on adding it to the acid, secondary products are largely formed. The mixture is poured into water, neutralised with calcium carbonate, and filtered; barium chloride is then added to the filtrate, whereby barium nitrophenolsulphonate is precipitated, from which the free acid and other salts may readily be prepared. Paranitrophenolorthosulphonic acid, $C^6H^3.OH.NO^2.SO^3H + 3H^2O$, crystallises in slender needles or large well-formed colourless prisms, very soluble in water. The *potassium salt*, $C^6H^3.OH.NO^2.SO^3K$, crystallises in colourless prisms, slightly soluble in water; the *dipotassium salt*, $C^6H^3.OK.NO^2.SO^3K + H^2O$, in orange-coloured prismatic needles which are very soluble in water. The *sodium salt*, $C^6H^3.OH.NO^2.SO^3Na + 2H^2O$, forms colourless crystals; the *disodium salt*, $C^6H^3.ONa.NO^2.SO^3Na + 2H^2O$, yellow crystals. The *calcium salt*, $(C^6H^3.NO^2.SO^3)^2Ca + 5H^2O$, crystallises in aggregates of yellow needles; the *barium salt*, $(C^6H^3.NO^2.SO^3)^2Ba + 2H^2O$, in yellow prisms.

Orthonitrophenolparasulphonic acid, $C^6H^3.OH.NO^2.SO^3H$ (1 : 2 : 4).—The potassium and sodium salts of this acid (1st Suppl. 925) are most readily obtained by the action of dilute nitric acid on potassium and sodium phenolparasulphonate (Schmitt a. Glutz, *Deut. Chem. Ges. Ber.* ii. 51; Körner, *Gazzetta chimica italiana*, 1872, ii. 444). Together with this acid, there appears to be produced a small quantity of an isomeric compound when it is prepared by the action of sulphuric acid on orthonitrophenol (Armstrong a. Brown, *Deut. Chem. Ges. Ber.* vii. 923).

Dinitrophenolsulphonic acids, $C^6H^2.OH.(NO^2)_2.SO^3H$.—According to Post (*ibid.* vii. 1323) both the above-described nitrophenolsulphonic acids may be converted into corresponding dinitrophenolsulphonic acids by careful nitration. He states also that phenoldisulphonic acid yields a dinitrophenolsulphonic acid on nitration.

Amidophenolsulphonic Acids. *Paramidophenolorthosulphonic acid*, $C^6H^3.OH.NH^2.SO^3H$ (1 : 2 : 4), is produced on adding paramidophenol hydrochloride to fuming sulphuric acid, in which it dissolves with evolution of heat; the mixture is heated a short time on the water-bath, and then poured into water, when almost the whole of the paramidophenolorthosulphonic acid separates as a snow-white powder (Post, *ibid.* vi. 397). The same compound appears to be obtained on reducing paranitrophenolorthosulphonic acid with tin and hydrochloric acid (Post), and it is also formed by the action of sulphurous acid or sodium-hydrogen sulphite on dichloropara-diazophenol (Schmitt a. Bennewitz). It crystallises in minute cubes and fine soft silky needles; the cubes, which first separate from the hot solution, but in a relatively very small quantity, are probably anhydrous, whereas the needles contain 1 mol. of water. It is very slightly soluble in cold water, 1 pt. requiring for solution about 2,800 pts. of water at 15°. A slight decomposition takes place on boiling the solution, which assumes a dark-red colour, but this is entirely prevented by the presence of a reducing agent, such as sulphurous acid or stannous chloride. Paramidophenolorthosulphonic acid does not combine with acids, but yields metallic salts; these salts, however, are readily decomposed, and it is not possible to obtain them pure from the acid and the metallic carbonates. The *barium salt*, $(C^6H^3.NH^2.SO^3)^2Ba$, is obtained on the addition of barium chloride to an ammoniacal solution of the acid in the form of a crystalline precipitate, consisting of aggregates of small plates.

Orthoamidophenolparasulphonic acid, $C^6H^3.OH.NH^2.SO^3H$ (1 : 2 : 4), is obtained by the action of sulphuric acid on orthoamidophenol hydrochloride (Post, Bennewitz), and on reduction of orthonitrophenolparasulphonic acid (Post). It crystallises in large colourless crystals like those of calc spar, containing $\frac{1}{2}$ mol. of water; it is more soluble than its isomeride, water at 14° dissolving about .01 p.c. The aqueous solution decomposes on evaporation, unless this be conducted in an atmosphere of hydrogen.

Diazophenolsulphonic Acids. The above-described amidophenolsulphonic acids are converted into the corresponding diazo-acids when suspended in water and treated with nitrous acid (Bennewitz, *J. pr. Chem.* [2], viii. 52). *Paradiazophenolorthosulphonic acid*, $C^6H^3\begin{matrix} N=N-OH \\ OH \\ SO^3H \end{matrix}$, crystallises in colourless or pink glistening

rhombic plates; it is difficultly soluble in cold, but more soluble in hot water; and it may be crystallised from the hot aqueous solution, which, however, gradually becomes red on boiling. The same compound is obtained on dissolving the amido-acid in nitric acid, and on warming it with nitric acid and urea. It is reconverted by the action of nascent hydrogen on an acid solution into the amido-acid. It does not unite with acids, but furnishes with bases a series of highly unstable salts decomposing even in the cold.

The diazo-acid from orthoamidophenolparasulphonic acid crystallises in yellowish needles; it is far more soluble in water, and much less stable than the para-diazo-compound.

Chloronitrophenolsulphonic Acids. *Potassium parachlororthonitrophenolorthosulphonate*, $C^6H^2Cl.NO^2.OH.SO^3K$, is obtained by the action of dilute nitric acid on potassium parachlororthosulphonate; it crystallises in yellow needles, difficultly soluble in cold water. It is converted by nitric acid into chloro- β -dinitrophenol (m. p. 81°). The *dipotassium salt*, $C^6H^2Cl.NO^2.OK.SO^3K$, forms magnificent long red needles, easily soluble in water (Armstrong a. Prevost, *Deut. Chem. Ges. Ber.* vii. 404).

Potassium orthochlororthonitrophenolparasulphonate, $C^6H^2Cl.NO^2.OH.SO^3K + \frac{1}{2}H^2O$, is formed by the action of weak nitric acid on potassium diorthochlorophenolparasulphonate; it crystallises in tufts of pale-yellow silky needles, very soluble in warm water, slightly soluble in cold. It yields chloro- α -dinitrophenol (m. p. 110°–111°) on treatment with nitric acid, and is converted into dichlororthonitrophenol (m. p. 121°) by the action of chlorine on its aqueous solution. The *dipotassium salt*, $C^6H^2Cl.NO^2.OK.SO^3K$, crystallises in orange-red six-sided plates, extremely soluble in hot water, moderately in cold (Armstrong, *Chem. Soc. J.* 1871, 1117). The potassium chlorophenolsulphonate obtained by Armstrong a. Prevost, by acting on potassium orthochlorophenolparasulphonate with weak nitric acid, is probably the same compound. A chlororthonitrophenolparasulphonic acid is produced by the action of chlorine on an alcoholic solution of orthonitrophenolparasulphonic acid, but has not yet been fully examined (Armstrong a. Brown, *ibid.* 1872, 872).

Bromonitrophenolsulphonic Acids. The potassium salts of bromonitrophenolsulphonic acids have been obtained: 1. By the action of nitric acid on potassium diorthobromophenolparasulphonate. 2. By similar treatment of potassium orthobromophenolparaorthodisulphonate. 3. By the action of bromine on an alcoholic solution of the orthonitrophenolsulphonic acids. 4. By nitrating the potassium salts of parabromo- and orthobromophenolsulphonic acids (Armstrong; Armstrong a. Brown; Armstrong a. Prevost, *Chem. Soc. J.* 1872, 857–872; *Deut. Chem. Ges. Ber.* vii. 404, 924). 5. By acting on an alcoholic solution of paranitrophenolorthosulphonic acid (Post, *ibid.* vii. 169) with bromine. These compounds have as yet, however, been comparatively little studied.

Iodonitrophenolsulphonic Acids. *Orthiodorthonitrophenolparasulphonic acid*, $C^6H^2I.NO^2.OH.SO^3H$ (1 : 2 : 4 : 6), is produced when iodine and mercuric oxide are added to an alcoholic solution of orthonitrophenolparasulphonic acid (Armstrong a. Brown, *Chem. Soc. J.* 1872, 869). The *potassium salt*, $C^6H^2I.NO^2.OH.SO^3K$, crystallises in difficultly soluble yellow scales, much resembling chlornil; these consist of aggregates of short needles; it is converted into potassium orthobromonitrophenolparasulphonate by the action of 1 mol. of bromine. The *dipotassium salt*, $C^6H^2I.NO^2.OK.SO^3K$, forms deep red prisms easily soluble in water. The *barium salt*, $(C^6H^2I.NO^2.SO^3)^2Ba + 4H^2O$, is precipitated in the form of pale yellow silky needles on the addition of barium chloride to a solution of the potassium salt.

Orthiodoparanitrophenolorthosulphonic acid, $C^6H^2I.NO^2.OH.SO^3H$ (1 : 2 : 4 : 6), is formed, together with diorthiodoparanitrophenol (m. p. 157°), by the action of iodine and mercuric oxide on an alcoholic solution of paranitrophenolorthosulphonic acid (Post a. Brackebusch, *Deut. Chem. Ges. Ber.* vii. 167). The *calcium salt*, $(C^6H^2I.NO^2.SO^3)^2Ca^2 + 6H^2O$, forms coarse yellow needles. The *dibarium salt* crystallises in long yellow needles; the *ammonium salt* is difficultly soluble in water; the *lead salt* is obtained as a yellow crystalline precipitate on the addition of lead acetate to a solution of the calcium salt.

'CONSTITUTION' OF THE PHENOL DERIVATIVES.

The prefix *ortho* was originally applied by Körner, in the case of the isomeric di-derivatives of benzene, simply to denote the compound which formed the chief product of the action of a reagent on a mono-derivative of benzene; thus he found that the chief product of the action of iodine on phenol was an iodophenol yielding hydroquinone on fusion with potassium hydrate; to this he gave the name orthiodophenol, and it became the practice to term all such di-derivatives as could be more or less directly referred to hydroquinone, *ortho*-derivatives. The iodophenol which he succeeded in obtaining from the so-called paranitraniline formed from ordinary dinitrobenzene, gave resorcin on fusion with potassium hydrate, and consequently resorcin, and all bodies which were considered as belonging to the same series of isomerides, were termed *para*-derivatives. The third iodophenol, formed in small quantity together with orthiodophenol, gave pyrocatechin on fusion with potassium hydrate; pyrocatechin and those di-derivatives which could be classed in a series with it were then termed *meta*-derivatives. Later on it became usual to associate with the terms *ortho*, *para*, and *meta*, certain conceptions as to the relative positions occupied by the radicles which had been introduced in place of hydrogen into benzene, Kekulé's theory of the 'constitution' of benzene being taken as the basis of argument, and the 'positions' denoted by figures; thus:

Graebe's researches on naphthalene (1st Suppl. 198 n. 212) led to the assumption that in phthalic acid, $C^6H^2(COOH)^2$, the two carboxyls are in the position 1 : 2, and Baeyer pointed out that the formation of mesitylene, $C^6H^2(CH^3)^3$, from acetone necessitates the assumption that the three methyl-groups occupy the positions 1 : 3 : 5, and hence that isoxylene, $C^6H^4(CH^3)^2$, which yields isophthalic acid on oxidation, has the methyl-groups in the position 1 : 3; accordingly, since phthalic acid is 1 : 2, and isophthalic, 1 : 3, terephthalic acid is of necessity 1 : 4. Hydroquinone, pyrocatechin, and resorcin were then considered to belong respectively to the same series as phthalic acid, isophthalic acid, and terephthalic acid, and these three acids have gradually usurped the place of the three dioxybenzenes as standards of reference, members of the phthalic or 1 : 2 series being commonly termed *ortho*-derivatives, those of the isophthalic or 1 : 3 series, *meta*-derivatives, and those of the terephthalic or 1 : 4 series, *para*-derivatives. Körner, however, is singular in using these prefixes in an opposite sense: thus he terms the 1 : 4 derivatives *ortho*-compounds, the 1 : 3 derivatives *para*-compounds, and the 1 : 2 derivatives *meta*-compounds (*Gazzetta chimica italiana*, 1874, 316).

All recent researches tend to confirm the hypothesis that the carboxyls in phthalic, isophthalic, and terephthalic acids are respectively in the positions 1 : 2 or 1 : 6, 1 : 3 or 1 : 5, and 1 : 4 (see Ladenburg, *Deut. Chem. Ges. Ber.* ii. 140; v. 322; vii. 1133 n. 1684), but have necessitated the shifting of many compounds considered to belong to one or another of these three series; thus resorcin has been shown to belong to the isophthalic (1 : 3) series, and not to the terephthalic (1 : 4) series. Again, hydroquinone, which was long considered a member of the phthalic (1 : 2) series, is now placed in the 1 : 4 series. The proof that resorcin belongs to the isophthalic series is as follows. When toluene is nitrated, two nitrotoluenes are formed which it has been proved belong respectively to the *ortho* (1 : 2) and *para* (1 : 4) series, and both of these yield the same dinitrotoluene on further nitration; this dinitrotoluene consequently has the constitution 1 : 2 : 4; thus:

* It must not be forgotten that the *ortho*- and *meta*-positions are repeated, since the positions 2 and 6 correspond respectively to the positions 6 and 2.

Orthonitrotoluene.

Paranitrotoluene.

Orthoparanitrotoluene.

On oxidation dinitrotoluene furnishes a dinitrobenzoic acid which, on reduction, yields a diamidobenzene identical with that which is obtained by reducing dinitrobenzene; hence it follows that the nitro-groups in dinitrotoluene and dinitrobenzene are in relatively the same positions, i.e. 1 : 3 (Wurster, *Deut. Chem. Ges. Ber.* vii. 148). Dinitrobenzene may, however, as Körner has shown, readily be converted into resorcin, which consequently is also a member of the isophthalic (1 : 3) series. The connection of ordinary dinitrobenzene with isophthalic acid is further proved by the fact that the dibromobenzene (b. p. 219°), which may be obtained from the former by Griess's method (Körner, *Gazzeta chimica italiana*, 1874, 331), is converted by the action of sodium and ethyl chlorocarbonate, and subsequent saponification of the product, into isophthalic acid (Wurster, *Deut. Chem. Ges. Ber.* vi. 1486):

Nitrophenols.—One of the three nitrophenols is obtained from diinitrobenzene; it therefore belongs to the isophthalic (1 : 3) series.

The connection of the non-volatile nitrophenol (m. p. 110°) obtained on nitration of phenol with the terephthalic (1 : 4) series, is proved in a variety of ways. Thus it has been shown that crystalline dibromobenzene (m. p. 89°) is converted by the action of methyl iodo and sodium into a dimethyl-benzene yielding terephthalic acid on oxidation (v. Meyer, *Ann. Chem. Pharm.* clvi. 281); but crystalline dibromobenzene may be formed, by Griess's method, from the bromonitrobenzene (m. p. 125°) produced on nitrating bromobenzene, and from this bromonitrobenzene, nitrophenol (m. p. 110°) is readily produced by heating with potassium hydrate solution (v. Richter). Nitrophenol (m. p. 110°), as Salkowski has shown, may be converted into anisic acid, and hence into paraoxybenzoic acid, which, there can be no doubt, is a member of the terephthalic series. The connection of hydroquinone with the terephthalic series is therefore proved by the observation that it may be produced from paranitrophenol (Salkowski).

The above considerations show that the third nitrophenol (m. p. 46°) must of necessity belong to the phthalic (1 : 2) series; and direct proof of this is afforded by its conversion into the diamidobenzene melting at 99° (Salkowski), which has been proved to be a member of that series. Moreover, this assumption is the only one which enables us to account for the formation of α -dinitrophenol from it and from paranitrophenol, and the fact that both α - and β -dinitrophenol yield ordinary dinitrobenzene (1 : 3) when the OH group is removed. This is at once evident on inspection of the following symbols:

Paranitrophenol.

Orthonitrophenol.

 α -Dinitrophenol.

 β -Dinitrophenol.

The constitution of α - and β -dinitrophenol results from the observation that it is produced by nitration of α - and β -dinitrophenol:

 α -Dinitrophenol.

 β -Dinitrophenol.

Trinitrophenol.

Chloro- and Bromophenols.—Two of the monochlorophenols have been obtained from nitrophenols by displacing the nitro-group by chlorine, and thus the position of the chlorine determined. The three monochloroanilines have also been converted into the three corresponding chlorophenols, and the monobromophenols have been similarly prepared from the three monobromoanilines.

The constitution of the dichlorophenol melting at 42° – 43° is shown to be 1 : 2 : 4 by its formation from ortho- and para-chlorophenol, and that of the isomeric compound (m. p. 65°) to be 1 : 2 : 6, because it may be obtained from the dichloroparanitrophenol, which it will be shown later on is 1 : 2 : 4 : 6. Since both of these yield trichlorophenol on chlorination, this becomes 1 : 2 : 4 : 6 ; thus :

Ordinary dibromophenol corresponds with the dichlorophenol melting at 42° – 43° , and tribromophenol with trichlorophenol; this conclusion with regard to tribromophenol is confirmed by its conversion, when acted upon by phosphorus pentabromide, into the same tetrabromobenzene as may be obtained by displacing the NH_2 group of ordinary tribromoaniline by bromine; thus :

Chloronitro-, Bromonitro-, and Iodonitrophenols.—Since the chloro- and bromo-nitrophenols have been obtained on the one hand by nitrating the chloro- and bromo-phenols, and on the other by chlorinating or brominating the nitrophenols, we may readily infer their constitution, since the constitution of the nitro-, chloro-, and bromo-phenols is known. One or two examples will suffice in illustration:—Parachlorophenol yields, on nitration, a parachloronitrophenol (m. p. 86°) identical with one that is formed on chlorinating orthonitrophenol; it is therefore *parachloro-orthonitrophenol*. Paranitrophenol furnishes, when chlorinated, an isomeric paranitrochlorophenol (m. p. 110°), which may be obtained by nitrating orthochlorophenol, and is therefore *paranitro-ortho-chlorophenol*. A third nitrochlorophenol (m. p. 70°) is obtainable by nitration of orthochlorophenol, and since on further nitration it is converted into orthochloro- α -dinitrophenol, which is also obtained by nitrating orthochloroparanitrophenol, it must of necessity be an *ortho-chloro-orthonitrophenol*; thus :

Since the dichloronitrophenol obtained on chlorinating paranitrophenol may be converted, by displacing one of the atoms of chlorine by NO_2 by the action of nitric acid, into orthochloro- α -dinitrophenol, it follows that the two chlorine-atoms occupy in it the positions 2 and 6, and that consequently this also is the position of the chlorine-

atoms in the dichlorophenol (m. p. 65°), which is obtained on removing the nitro-group from paranitrodichlorophenol; thus:

Orthochloro- α -dinitrophenol.

Dichloroparanitrophenol.

Diorthochlorophenol (m. p. 65°).

The constitution of iodo- α -dinitrophenol is given by the following observations: 1. It may be obtained by iodating α -dinitrophenol, and 2. By the action of hydriodic acid on diazodinitrophenol from amidodinitrophenol or picramic acid, it being proved that it is one of the nitro-groups in the *ortho*-position which undergoes reduction when trinitrophenol is converted into amidodinitrophenol, by the fact that when amidodinitrophenol is converted into dinitrophenol by the action of ethyl nitrite, α -dinitrophenol is obtained; thus:

Trinitrophenol.

Amidodinitrophenol.

α -Dinitrophenol.

Iodo- α -dinitrophenol.

In the case of iodo- β -dinitrophenol the position of the nitro-group is given by its formation from β -dinitrophenol; the position of the iodine has not been directly established, but there can be no doubt that it is in the *para*-position, since the corresponding chloro- and bromo-dinitrophenols obtained by chlorinating and brominating β -dinitrophenol are also produced by nitrating parachloro- and parabromophenol:

β -Dinitrophenol.

Iodo- β -dinitrophenol.

The iodonitrophenol melting at 93° can only be orthiodoparanitrophenol, since it is converted into iodo- α -dinitrophenol on nitration; and since the isomeride melting at 109°-110°, produced from orthonitrophenol, also yields iodo- α -dinitrophenol on nitration, it is probably also an orthiodophenol derivative; thus:

Iodonitrophenol (m. p. 93°).

Iodonitrophenol (m. p. 109°).

Iodo- α -dinitrophenol.

Phenolsulphonic acids.—Of the two modifications of phenolsulphonic acid, the unstable modification is apparently shown to belong to the *ortho*-series (1 : 2) by its conversion into pyrocatechin on fusion with potassium hydrate. The isomeric acid (Kekulé's phenolparasulphonic acid) furnishes resorcin on similar treatment, but only in very small quantity; the conclusion that it belongs to the same series as resorcin

is therefore not justified by this result, especially as recent observations have shown that the reaction with fused potassium hydrate is not in all cases a trustworthy means of determining the constitution of a compound. Thus two isomeric bromophenols yield the same diorybenzene (resorcin) on fusion with potassium hydrate, and, on the other hand, two different observers have obtained different products from the same chlorophenol, Petersen having converted parachlorophenol into hydroquinone by fusing it with potassium hydrate, whereas Faust obtained resorcin. It has also recently been stated that the three isomeric bromobenzenesulphonic acids furnish resorcin on fusion with potassium hydrate (Limpricht, *Deut. Chem. Ges. Ber.* vii. 1352).

Kekulé's phenolparasulphonic acid is shown, however, to belong to the terephthalic (1 : 4) series by its conversion into parachlorophenol and paradichlorobenzene (m. p. 53°-54°), on distillation with phosphorus pentachloride (Barbuglia a. Kekulé, *ibid.* v. 875; vi. 943):

Assuming that when the haloïd-derivatives of the phenolsulphonic acids are converted into haloïd-nitrophenols by the action of nitric acid, the sulpho-group, SO^2H , is directly displaced by the NO^2 -group--and there is every reason to suppose that this is the case--the fact that the dichlorophenolsulphonic obtained from Kekulé's phenolparasulphonic acid yields, on nitration, a dichloronitrophenol identical with that obtained on chlorinating paranitrophenol, also proves that the sulpho-group in the acid in question is in the para-position. Similarly, since Kekulé's phenolmetasulphonic acid yields, when chlorinated, a dichlorophenolsulphonic acid which furnishes dichlororthonitrophenol on nitration, the sulpho-group in this acid may be supposed to occupy the ortho- (1 : 2) position; thus:

Phenoldisulphonic acid is shown to be 1 : 2 : 4 by its formation from phenolortho- and phenolpara-sulphonic acid.

The constitution of the haloïd and haloïd-nitro-phenolsulphonic acids is inferred from their formation from the haloïd-phenols, &c., and from their conversion into haloïd-nitrophenols of known constitution by the action of nitric acid.

The various haloïd-, nitro-, sulpho-, haloïd-sulpho-, haloïd-nitro-, nitro-sulpho-, and haloïd-nitro-sulpho-phenols of known constitution, which have been obtained from phenol, are arranged in the following table (p. 929). Each compound is represented merely by the radicle or radicles, by the substitution of which for hydrogen in phenol it is formed.

This table contains, with one or two exceptions, all the mono-, di-, and tri-derivatives as yet prepared from phenol. The number of phenol-derivatives obtained by indirect methods, and not included in the table, is also extremely small.

It is at once evident that the results here tabulated lead to two remarkable conclusions, viz.—

1. That the action of the halogens, of nitric acid, and of sulphuric acid, on phenol is similar, inasmuch as the same hydrogen-atoms are always displaced.
2. That the tendency of these agents is always to displace hydrogen in the *ortho*-positions (1 : 2 and 1 : 6), and the *para*-position (1 : 4), and but rarely to produce *meta*-derivatives. Thus, although it results from Körner's observations that meta-bromophenol may be obtained directly from phenol, its formation appears to be dependent upon certain conditions not yet understood. It is also not known at present whether meta-iodophenol is a constant product of the action of iodine on phenol. It appears not improbable, however, that the tendency to form the meta-derivative may, in the case of iodine, be considerable, and thus always lead to its production; but less strong in the case of bromine, and still less so in the case of chlorine, so that meta-derivatives are not formed by these in any quantity, except under peculiar conditions. There is no evidence at present that with nitric or sulphuric acid there is any tendency to form meta-derivatives.

H. E. A.

PHENOL, HOMOLOGUES OF. The hydrocarbons homologous with benzene, which may be represented by the general formula, $C^aH^{4-m}(C^bH^{2n+1})^m$,* are capable of yielding two metameric series of monohydric alcohols; thus toluene, $C^6H^5.CH^3$, is convertible on the one hand into the cresols, $C^6H^4(OH).CH^3$, and on the other into benzyl alcohol, $C^6H^5.CH^2(OH)$, which is metameric with the cresols. The alcohols of the former class, which are termed *phenols*, on account of the resemblance they bear to phenol, the first term of the series, may be represented by the general expression, $C^aH^{4-m}(C^bH^{2n+1})^m$, the alcohols of the latter class, which for want of a better name may be termed *alcohols of the benzylic series*, being represented by the general formula, $C^aH^{4-m} \left\{ \begin{matrix} C^bH^{2n}.OH \\ (C^bH^{2n+1})^m \end{matrix} \right.$. In the case of the first term of the phenol series, the value of n and m in the general formula above given is zero, and the highest possible value of m is doubtless 5; the limits within which n may vary have not yet been determined, and cannot be predicted. In the alcohols of the benzylic series, m in the first term equals 0, and cannot exceed 5; the lowest value of n , however, in the $C^aH^{2n}.OH$ group is 1. The limit of variation of n cannot be stated.

The following alcohols derived from hydrocarbons of the benzene series are known:—

Phenols, $C^aH^{4-m}(OH)(C^bH^{2n+1})^m$		b. p.	
C^6H^4O	Phenol or Oxybenzene	$C^6H^5.OH$	182
C^6H^4O	Paracresol or Paroxymethylbenzene	$C^6H^4.CH^3.OH$	200-205
	Metacresol or Metoxymethylbenzene		195-200
	Orthocresol or Orthoxymethylbenzene		185-186
C^6H^4O	Metaxyleneol (solid) or Oxymetadimethylbenzene	$C^6H^3(OH) \left\{ \begin{matrix} CH^3 \\ CH^3 \end{matrix} \right.$	216
	Xyleneol (liquid) or Oxydimethylbenzene		212
C^6H^4O	Ethylphenol (solid) or Paroxyethylbenzene		214-216
	Ethylphenol (liquid) or Orthoxyethylbenzene	$C^6H^4.C^2H^5.OH$	212
	Phlorol (?) Oxyethylbenzene		220
	(Thymol; α -Cymophenol or Oxyparamethylpropylbenzene		230
$C^{10}H^{14}O$	Carvacrol; β -Cymophenol or Oxyparamethylpropylbenzene	$C^8H^7(OH) \left\{ \begin{matrix} CH^3 \\ C^2H^5 \end{matrix} \right.$	233

* The value of m may be 0 and cannot exceed 5; when there are several C^bH^{2n+1} groups in the hydrocarbon, the value of n may be the same or different in each of these.

Orthonitroparacresol is readily converted by nitric acid into dinitroparacresol (m. p. 84°); the (probably) isomeric nitroparacresol yields a different substance (Armstrong).

Orthoamidoparacresol, $C^6H^3.CH^3.NH^2.OH$ (Wagner, *Deut. Chem. Ges. Ber.* vii. 1270), is prepared by reducing orthonitroparacresol (m. p. 33°) with tin and hydrochloric acid; it is separated from the hydrochloride by ammonia and recrystallised from boiling water, and is thus obtained in white glistening scales almost insoluble in cold water, but easily soluble in alcohol and ether. It separates from the solution in ether in large rhombic crystals. The *hydrochloride* forms long white needles, easily soluble in water and alcohol, difficultly soluble in ether. A platinum double salt could not be obtained.

Orthoamidoparacresol hydrochloride is converted into orthodiazoparacresol hydrochloride by ethyl nitrite, but on account of its easy solubility the diazo-compound is difficult to isolate. It yields with platinum chloride a double salt, $C^6H^3.ON^2.Cl.FtCl^4$, resembling ammonium-platinum chloride in appearance (Wagner). On dry distillation this double salt furnishes a chlorocresol.

Dinitroparacresol, $C^6H^3.CH^3.(NO^2)^2.OH$ (? $OH : NO^2 : CH^3 : NO^2 = 1 : 2 : 4 : 6$).—This compound, which may be obtained by the action of nitrous acid on paratoluidine (1st Suppl. 508) is also produced—1. By nitration of orthonitroparacresol (Armstrong a. Field).—2. By nitration of potassium paracresolorthosulphonate (Armstrong a. Field; Pechmann, *Ann. Ch. Pharm.* clxxiii. 205).—3. By heating dinitroparacetotoluidine with sodium hydrate solution (Wagner). It crystallises in lemon-yellow needles, melting at 84°, slightly soluble in water, very soluble in alcohol and ether. When treated with even the strongest nitric acid, it does not yield a trinitro-derivative (Armstrong, *Deut. Chem. Ges. Ber.* vii. 406).

Potassium dinitroparacresol, $C^6H^3.(NO^2)^2.OK$, crystallises in long carmine-red flattened needles, easily soluble in hot, but much less soluble in cold water. The *ammonium derivative* forms anhydrous red needles. The *barium derivative*, $[C^6H^3.(NO^2)^2.O]^2Ba$, separates in fine yellow difficultly soluble needles. The *lead derivative* also forms fine yellow anhydrous needles. The *silver derivative*, $C^6H^3.(NO^2)^2.OAg$, crystallises in beautiful carmine-red needles (Pechmann).

Paracresolorthosulphonic acid, $C^6H^3.CH^3.OH.SO^3H$ ($OH : SO^3H : CH^3 = 1 : 2 : 4$). Pechmann's *Paracresolmetasulphonic acid*, $CH^3 : SO^3H : OH = 1 : 3 : 4$. *Paracresolsulphuric acid* (1st Suppl. 566).—According to Barth (*Ann. Chem. Pharm.* cliv. 364), and Biedermann (*Deut. Chem. Ges. Ber.* vi. 326), protocatechuic acid, $C^6H^4(OH)^2.CO^2H$, is formed when potassium paracresolsulphonate from paracresol is fused with potassium hydrate; Pechmann (*Ann. Ch. Pharm.* clxxiii. 204) using that prepared from paratoluidinemetasulphonic acid ($OH^2 : SO^3H : NH^2 = 1 : 3 : 4$) obtained chiefly paroxybenzoic acid, and only traces of protocatechuic acid.

The action of bromine on potassium paracresolorthosulphonate gives rise to the formation, first of bromo- then of dibromoparacresolsulphonate, which, by the continued action of the bromine, appears to be converted into tribromoparacresol. The dibromosulpho-salt is the main product, however, even when only 1 mol. of bromine is added to 1 mol. of the salt (Armstrong a. Field). Dilute nitric acid converts potassium paracresolorthosulphonate into nitroparacresolorthosulphonate, which, by the continued action of the acid, yields dinitroparacresol (m. p. 84°) (Armstrong a. Field). Little, however, is at present known of these derivatives.

Paracresolmetasulphonic acid, $C^6H^3.CH^3.OH.SO^3H$ ($OH : SO^3H : CH^3 = 1 : 3 : 4$). Jensen's *Paracresolorthosulphonic acid*, ($CH^3 : SO^3H : OH = 1 : 2 : 4$).—This acid is produced by heating the diazo-derivative of paramidotolueneorthosulphonic acid ($CH^3 : SO^3H : NH^2 = 1 : 3 : 4$) from paranitrotoluene and sulphuric acid with water (Jensen, *Ann. Chem. Pharm.* clxxii. 230). It crystallises from water in long white needles with 5 mols. of water, which melt at 98.5°; on exposure over sulphuric acid they lose the water of crystallisation and then melt at 187°–168°. All the salts of this acid are very soluble and could not be obtained in a crystalline state; the barium salt is not precipitated by barium hydrate.

A nitroparacresolmetasulphonic acid is produced when the nitrodiazo-acid formed by the action of fuming nitric acid on paramidotolueneorthosulphonic acid is heated with water. An orthobromoparacresolmetasulphonic acid may be similarly prepared from metabromoparamidotolueneorthosulphonic acid (Weckwarth, *Ann. Chem. Pharm.* clxxii. 201).

Chlorocresol, $C^6H^3.Cl.CH^3.OH$.—By passing chlorine into heated cresol (from coal-tar) and fractionally distilling the product, Biedermann (*Deut. Chem. Ges. Ber.* vi. 326) obtained a chlorocresol crystallising in long needles, which melt at 66°, and boil without decomposition at about 240°. The cresol employed evidently contained a considerable proportion of paracresol, so that this chlorocresol may be a paracresol derivative.

By the action of iodine and iodic acid in an alkaline solution on the same cresol in the proportions required to form an iodocresol, Biedermann obtained an oily product, which he decomposed with alcoholic potassium hydrate at 250°-300°. The product was an amorphous yellowish-red substance, which, on analysis, gave numbers agreeing approximately with those required by the formula $\text{C}^6\text{H}^3\text{CH}^2\text{OH}\{\text{O}\}$.

Constitution of the Paracresol derivatives.—The constitution of the volatile nitro-paracresol is given by its formation from nitroparatoluidine. Thus Bülstein a. Kuhlberg have shown (*Ann. Chem. Pharm.* clv. 1) that the nitroparatoluidine procurable from aceto-paratoluidine by nitration, &c., yields, on removal of the amido-group, a metanitrotoluene (1 : 3), which enables us to infer the constitution of nitrotoluidine, and consequently of nitroparacresol, to be as follows :

The very great resemblance which nitroparacresol bears to the volatile orthonitrophenol serves to confirm this conclusion that the nitro-group is in the ortho-position.

In dinitroparacresol (m. p. 84°) the nitro-groups probably occupy the ortho-positions : firstly, because of the close resemblance which it bears to β -dinitrophenol ; and secondly, because, as previously pointed out, in the case of nearly all phenol derivatives directly prepared from phenol, the para- and ortho-positions are occupied, and not the meta-positions :

The cresolsulphonic formed directly from paracresol has the sulpho-group in the ortho-position. This is shown by its formation from paramidotoluenemetasulphonic acid, which, on removal of the NH^2 group, yields toluenemetasulphonic acid (Pechmann) ; thus :

In a similar manner the isomeric acid is shown to have the sulpho-group in the meta-position, by its formation from an amidotoluenesulphonic acid which yields tolueneorthosulphonic acid (Jensen) ; thus :

METACRESOL, $C^6H^4.O = C^6H^4.CH^3.OH$ (1 : 3).—Southworth (*Ann. Chem. Pharm.* clxviii. 267) recommends the use of 50 grams of phosphoric anhydride in place of the 35 grams employed by Engelhardt a. Latschinoff (*1st Suppl.* 507) to decompose 100 grams of thymol. By the action of potassium chlorate and hydrochloric acid, meta-cresol is converted into *dichlorotoluenetaquinone*, $C^6H^2.Cl^2O^2$ (Southworth).

Metaresolsulphonic acid, $C^6H^4.CH^3.OH.SO^3H$.—When the metabromotolueneortho-sulphonic acid, prepared by Griess's method from the metabromoparamidotoluene-orthosulphonic acid formed on adding bromine to a solution of paramidotolueneortho-sulphonic acid, is treated with moist silver oxide, the bromine is displaced by OH, and a metaresolsulphonic acid produced, the potassium salt of which crystallises in beautiful coarse needles. Orthobromotoluenemetasulphonic acid is similarly acted upon (Weekwarth, *Ann. Chem. Pharm.* clxxii. 201).

ORTHO-CRESOL, $C^6H^4.O = C^6H^4.CH^3.OH$ (1 : 2).—Kekulé (*Dent. Chem. Ges. Ber.* vii. 1006) has obtained pure orthocresol by heating carvacrol, the isomeride of thymol, with phosphoric anhydride, and fusing the resulting cresyl phosphate with potassium hydrate; and by Griess's method from orthotoluidino. It melts at 31° – $31^{\circ}5'$, and boils at 185° – 186° . The benzoyl-derivative remains liquid even when very strongly cooled. Orthocresotol, from pure orthocresol, melts at 163° – 164° , and not, as stated by Engelhardt a. Latschinoff (*1st Suppl.* 508), at 114° .

The cresol obtained by Körner (*1st Suppl.* 507) from bromophenol appears to have been metaresol (1 : 3). Henry's dichlorocresol (*ibid.*), from salicylic aldehyde, is an orthocresol (1 : 2) derivative.

Commercial cresol, from coal-tar, appears always to contain paracresol and orthocresol in varying proportions mixed with more or less phenol (Armstrong a. Field).

Orthocresolparasulphonic acid, $C^6H^4.CH^3.OH.SO^3H$ (OH : CH^3 : SO^3H = 1 : 2 : 4), is produced on heating orthodiazotolueneparasulphonic acid with water, and, but in a much purer form, by adding the diazo-compound to gently warmed fuming sulphuric acid (Hayduck, *Ann. Chem. Pharm.* clxxii. 204; clxxiv. 343). The *barium salt*, $(C^6H^4.OH.SO^3)^2Ba + 1\frac{1}{2}H^2O$, is extremely soluble; it crystallises in aggregates which, under the microscope, are seen to consist of monoclinic prisms. The *potassium salt*, $C^6H^4.OH.SO^3K + \frac{1}{2}H^2O$, dissolves in water in all proportions, and is also very easily soluble in alcohol; from a saturated solution in anhydrous alcohol it separates as a yellowish crystalline powder, and from an aqueous alcoholic solution, on slow evaporation, in groups of short needles. It yields salicylic acid when fused with potassium hydrate.

Ethylorthocresolparasulphonic acid, $C^6H^4.CH^3.OC^2H^5.SO^3H$, is formed when orthodiazotolueneparasulphonic acid is boiled with absolute alcohol. The *potassium salt*, $C^6H^4.(OC^2H^5).SO^3K + H^2O$, crystallises in glistening white needles united in lamellae; it is very soluble in water. The *barium salt*, $[C^6H^4.(OC^2H^5).SO^3]^2Ba + 3H^2O$, separates from concentrated solutions in aggregates of microscopic needles, and from less concentrated solutions in needles; it is somewhat difficultly soluble in cold, but easily soluble in hot water. The *lead salt*, $[C^6H^4.(OC^2H^5).SO^3]^2Pb + 3H^2O$, forms long hair-fine white glistening needles, united in groups; it is easily soluble in hot water. The *chloride*, $C^6H^4.(OC^2H^5).SO^3Cl$, prepared from the potassium salt and phosphorus pentachloride, is a yellowish oil, from which rhombic plates separate on standing over sulphuric acid; ammonia converts it into the *amide*, $C^6H^4.(OC^2H^5).SO^3NH^2$, which crystallises in glistening plates melting at 137° , difficultly soluble in hot water (Hayduck).

Methylorthocresolparasulphonic acid, $C^6H^4.CH^3.OCH^3.SO^3H$, is similarly prepared with the aid of methyl alcohol. The *barium salt*, $[C^6H^4.(OCH^3).SO^3]^2Ba + 2H^2O$, crystallises in small glistening plates, somewhat more soluble in water than the ethyl compound (Hayduck).

Nitroorthocresolparasulphonic acid, $C^6H^4.CH^3.NO^2.OH.SO^3H$, is obtained by heating nitroorthodiazotolueneparasulphonic acid with water or sulphuric acid. The *barium salt*, $[C^6H^4.(NO^2).OHSO^3]^2Ba + 5H^2O$, crystallises in hard yellow monoclinic prisms of considerable size; it is easily soluble in water. The *dibarium salt*, $[C^6H^4.(NO^2).SO^3]^2Ba^2 + 6\frac{1}{2}OH^2$, forms tufts of orange-red needles, easily soluble in hot water (Hayduck).

Dibromorthocresolparasulphonic acid, $C^6H^4.Br^2.OH.SO^3H$.—This acid is obtained by heating dibromorthodiazotoluene-sulphonic acid, prepared from the dibromo-acid formed from bromine and orthamidotoluene-sulphonic acid, with water. The *barium salt*, $[C^6H^4.Br^2.OHSO^3]^2Ba + 8\frac{1}{2}H^2O$, forms easily soluble glistening plates. The *potassium salt*, $C^6H^4.Br^2.OHSO^3K + H^2O$, crystallises similarly (Hayduck).

XYLENOLS, $C^6H^{10}O = C^6H^4(CH^3)_2OH$ (see 1st Suppl. 1128).

ETHYLPHENOLS, $C^6H^{10}O = C^6H^4.C^2H^5.OH$.—The crystalline ethylphenol obtained by Fittig & Kiesow and by Beilstein & Kuhlberg (*ibid.* 916 *) on fusing potassium ethylbenzenesulphonate, $C^6H^4.C^2H^5.SO^3K$, with potassium hydrate, in oil probably corresponds with paraeresol, and the liquid phenol with orthoeresol. When heated with phosphoric anhydride, solid ethylphenol is converted into a phenylphosphate and ethylene is evolved (Chrutschoff, *Deut. Chem. Ges. Ber.* v.i. 1165):

PHLOROL, **PHLORETOL**, $C^6H^{10}O = (?)C^6H^4.C^2H^5.OH$ (v. 493; 1st Suppl. 928).—Körner & Corbetta (*Deut. Chem. Ges. Ber.* vii. 1731) have recently shown that when methylphloreotic acid is oxidised it is converted into anisic acid, thus proving phloreotic acid to be a phenolpropionic acid, $C^6H^4(OH).C^2H^4.COOH$. Since phlorol is obtained on distilling barium phloretate with caustic lime, this observation appears to prove that phlorol is an ethylphenol in which the ethyl and OH-group occupy the positions 1 : 4; phlorol, however, according to Hlasiwetz's description, has very different properties from those of crystalline ethylphenol, which, there is much reason to believe, is a para-derivative.

THYMOL, **α -CYMOPHENOL**, **OXYPARAMETHYLPROPYLBENZENE**, $C^6H^{14}O = C^6H^4.OH \left\{ \begin{smallmatrix} C^3H^7 \\ CH^3 \end{smallmatrix} \right\}$ ($OH : CH^3 : C^3H^7 = 1 : 3 : 6$).—According to Carstanjen (*J. pr. Chem.* [2], iii. 53) the thymoöl which Lallemand prepared by oxidising thymolsulphonic acid with manganic peroxide and sulphuric acid (v. 792), and to which he gave the formula $C^{12}H^{16}O^2$, is in reality thymoquinone, $C^{10}H^{12}O^2$, which on reduction yields Lallemand's thymoöl or thymohydroquinone, $C^{10}H^{12}(OH)^2$. The diamidothymol obtained from dinitrothymol (v. 795) yields oxythymoquinone, $C^{10}H^{14}(OH)O^2$, on oxidation. When thymol is distilled with phosphorus pentachloride, a chlorocymene, $C^{10}H^{14}Cl$, is produced, which, on reduction with sodium amalgam, yields cymene, $C^{10}H^{14}$ (b. p. 174°–176°); this cymene is converted, on oxidation, into terephthalic acid (Carstanjen). When thymol is distilled with phosphorus pentasulphide, it furnishes cymene identical with camphor-cymene and the mercaptan, $C^{10}H^{12}.SH$ (α -thiocymene), corresponding with thymol (Fittica, *Deut. Chem. Ges. Ber.* vi. 938; *Ann. Chem. Pharm.* clxii. 303).

CARVACROL, **β -CYMOPHENOL**, **OXYPARAMETHYLPROPYLBENZENE**, $C^6H^{14}O = C^6H^4.OH \left\{ \begin{smallmatrix} C^3H^7 \\ CH^3 \end{smallmatrix} \right\}$ ($OH : CH^3 : C^3H^7 = 1 : 2 : 5$).—When carvol (i. 808) is warmed with a small quantity of orthophosphoric acid, much heat is evolved, and it is converted into carvacrol (Kekulé & Fleischer, *Deut. Chem. Ges. Ber.* vi. 1087). Carvacrol is also produced when camphor is heated for some time with $\frac{1}{2}$ of its weight of iodine (*ibid.* 934). The compound thus obtained from carvol and camphor is identical with Post & Müller's cymophenol, formed on fusing the potassium salt of cymene-sulphonic acid (from camphor-cymene) with potassium hydrate (1st Suppl. 1089).

Carvacrol boils at 232°–232.5° (at 236°–237° when the entire mercury column of the thermometer is immersed in the vapour); when distilled with phosphorus trisulphide or pentasulphide it yields cymene and β -thiocymene, more of the latter being obtained if the pentasulphide be employed. The thiocymene is isomeric with that formed from thymol. When carvacrol is heated with phosphoric anhydride, propylene is evolved; the residue yields orthoeresol when decomposed with potassium hydrate, &c. Phosphorus pentachloride converts it into chlorocymene, boiling at 214°.

Carvacrolsulphonic acid is crystalline and yields crystalline salts; when oxidised by manganic oxide and sulphuric acid, it furnishes thymoquinone identical with that obtained from thymol. The acid, $C^6H^4.CH^3.C^3H^7.OH.CO^2H$, produced on treating carvacrol with sodium and carbonic anhydride, melts at 133°–134°, the isomeric acid from thymol melting at 120°.

Constitution of the Cymophenols.—Thymol and carvacrol are both derived from the same methylpropylbenzene or cymene. This is proved by the conversion of thymol by the action of phosphorus pentasulphide into cymene identical with that contained in Ptychotis oil, and which can be produced by heating camphor with phosphorus pentasulphide or pentoxide, from which Müller & Post respectively obtained carvacrol. This methylpropylbenzene is shown to contain methyl and normal propyl in the para-position, by its formation from crystalline bromotoluene, normal propyl bromide and sodium (Fittica). Finally, the position of the OH-group is determined by the conversion of thymol into metaeresol, and of carvacrol into orthoeresol; thus:

* The name *phenetol*, and the formula $C^6H^4.(C^2H^5)_2O$, is there wrongly assigned to this compound.

BENZYL ALCOHOL, $C^6H^5O = C^6H^5.CH^2(OH)$.—See vol. i. p. 578, and 1st *Suppl.* 334; also p. 177 of this volume.

PARATOLYL ALCOHOL, $C^6H^4O = C^6H^4(CH^3)CH^2(OH)$.—This alcohol, which is described in vol. v. p. 869, has the methyl and $CH^2(OH)$ -group in the para-position, since it is obtained by the action of nascent hydrogen on the aldehyde of ordinary *p*-*paratoluic acid*, $C^6H^4.CH^3.COOH$ ($CH^3 : COOH = 1 : 4$).

SECONDARY PHENYLETHYL ALCOHOL, $C^6H^4O = C^6H^4.CH(OH).CH^3$.—This alcohol is produced by the action of sodium-amalgam on a dilute alcoholic solution of acetophenone, $C^6H^5.CO.CH^3$, together with the corresponding pinacone (Emmerling a. Engler, *Deut. Chem. Ges. Ber.* vi. 1005); and by saponification of the acetate formed by the action of bromethylbenzene, $C^6H^5.CHBr.CH^3$, on silver acetate (Radziszewski, *ibid.* vii. 140). It is a colourless, highly refractive liquid, possessing an extremely unpleasant odour. It boils at 202° – 203° . By the action of hydrobromic acid it is converted into bromethylbenzene; and by the action of hydrochloric acid into chlorethylbenzene boiling at about 194° . The properties of the chlorethylbenzene thus obtained agree fairly with the description given by Fittig of the chlorethylbenzene formed by chlorinating ethylbenzene, but since the latter furnishes hydrocinnamic acid when the chlorine is replaced by carboxyl (1st *Suppl.* 469), the two compounds must be isomeric (Emmerling a. Engler).

PRIMARY PHENYLPROPYL ALCOHOL, $C^6H^3O = C^6H^3.CH^2.CH^2(OH)$.—This alcohol is present in storax, probably as cinnamic ether, and is contained in considerable quantity in commercial cinnamic alcohol. It may be produced by the action of nascent hydrogen on cinnamic alcohol (Fittig, *Deut. Chem. Ges. Ber.* vi. 215). It is a colourless thick liquid, of sp. gr. 1.008 at 18° , which boils at 235° ; on oxidation it yields hydrocinnamic acid.

Phenylpropyl acetate, $C^6H^3.O.C^3H^5O$, is a yellowish, almost odourless liquid, much more mobile than the alcohol; it boils at 244° – 245° . Like the alcohol it does not solidify at -18° .

SECONDARY PHENYLPROPYL ALCOHOL, $C^6H^3O = C^6H^3.CH(OH).CH^2.CH^3$.—This alcohol is formed by the action of sodium-amalgam on a dilute alcoholic solution of propiophenone, $C^6H^5.CO.OH^2.CH^3$. It boils at 210° – 211° , but is partially decomposed (Barry, *Deut. Chem. Ges. Ber.* vi. 1008).

CUMIC or CUMINYL ALCOHOL, $C^6H^4O = C^6H^4.C^3H^7.OH(OH)$.—See vol. ii. p. 298. The propyl and $OH(OH)$ -group in this alcohol are in the para-position, since it ultimately furnishes terephthalic acid on oxidation.

SECONDARY PHENYLBUTYL ALCOHOL, $C^6H^3.CH(OH).CH^2.CH^2.CH^3$, is produced by the action of nascent hydrogen on phenylpropyl ketone, but has not yet been examined (*Deut. Chem. Ges. Ber.* vii. 1128).

SYCOMERYLIC ALCOHOL, C^6H^5O . See vol. v. p. 845.

H. E. A.

PHENOQUINONE, $C^{12}H^{10}O^4$ (see QUINONES).

PHENYL (DI-), $C^{12}H^{10}$. *Formation*.—1. By heating potassium phenate with potassium benzoate (Pfankuch, *J. pr. Chem.* [2], i. 451):—

2. By heating potassium phenate with oxalate (Pfankuch, *ibid.* iv. 35).

3. Together with anilino, acetone, and a small quantity of diphenylamine, by heating sodium phenate with acetanilide (Weith, *Deut. Chem. Ges. Ber.* vi. 966).

4. By heating phenanthrene-quinone with soda-lime (Graebe, *Ann. Ch. Pharm.* clxvii. 181):

Preparation.—Engelhardt a. Latschinoff (*Zeitschr. f. Chem.* [2], vii. 259) prepare this compound by mixing 780 grams of benzene with 25 grams of iodine and 1.256 grams of bromine. The reaction goes on quietly, but towards the end the heat of the water-bath has to be applied. On distillation, the portion boiling below 159° is collected separately, and, after drying and removing all traces of hydrobromic acid, 150 grams of sodium are added. If the reaction does not begin by itself, it is started by gentle heating, but as soon as it begins the mixture must be well cooled. The products consist of excess of benzene, diphenyl (of which 120 grams were obtained), and a liquid having a very high boiling point. In the retort there remains, besides sodium iodide, a black solid which can be volatilised by very strong heat.

Reactions.—Diphenyl is not altered by passing through a red-hot tube 3 feet long, filled with fragments of pumice (Dreher a. Otto, *Ann. Ch. Pharm.* cliv. 93).

By a solution of *chromic oxychloride* in glacial acetic acid, it is oxidised to benzoic acid (Carstanjen, *J. pr. Chem.* [2], i. 79).

With *formaldehyde* it produces a hydrocarbon which separates from chloroform in small crystals (Bayer, *Deut. Chem. Ges. Ber.* vi. 220).

Bromodiphenyl, $C^{12}H^8Br$ or $C^6H^5.C^6H^4Br$, is formed by adding bromine to a solution of diphenyl in carbon sulphide. It crystallises in laminae melting at 89° and boiling at 310° , and yields by oxidation parabromobenzoic acid, which is also formed by the oxidation of dibromodiphenyl (Engelhardt a. Latschinoff).

Chlorodiphenyl, $C^{12}H^8Cl$ = $C^6H^5.C^6H^4Cl$, is formed by distilling diphenyl-phenol with phosphorus pentachloride. It melts at 75° , and is converted by oxidation into parabromobenzoic acid (G. Schultz, *Deut. Chem. Ges. Ber.* vii. 52).

Nitro-, and **Amido-diphenyls** (Schultz, *loc. cit.*; Osten, *Deut. Chem. Ges. Ber.* vii. 170). **Mononitrodiphenyl**, $C^{12}H^9NO^2$ = $C^6H^5.C^6H^4NO^2$, is obtained by treating diphenyl with excess of strong nitric acid in the cold, or with the required quantity in a hot acetic acid solution (Schultz), or by adding 4 pts. of fuming nitric acid diluted with 44 pts. of glacial acetic acid to 40 pts. of acetic acid in which are suspended 5 pts. of diphenyl; the latter then dissolves, and after a short time crystals of nitrodiphenyl make their appearance (Osten). It is also produced by converting amidonitrophenyl into a diazo-compound, and boiling the latter with alcohol (Schultz).

Mononitrodiphenyl crystallises in long colourless needles, which are insoluble in water, easily soluble in chloroform, ether, and hot alcohol. It melts at 113° , volatilises at a high temperature, and boils at 340° .

Monamidodiphenyl, $C^{12}H^9NH^2$.—The hydrochloride of this base is produced by treating nitrodiphenyl with tin and hydrochloric acid; the tin is then removed by sulphuretted hydrogen, and after rendering the solution alkaline with sodium hydrate, the liberated base may be at once collected on a filter or distilled in a current of steam. It crystallises from dilute alcohol in thin glistening scales, which melt at 48° – 49° (Osten), at 49° – 50° (Schultz), and are readily soluble in alcohol. The *hydrochloride*, $C^{12}H^9NH^2.HCl$, crystallises in colourless scales which are soluble in water. The *sulphate*, $(C^{12}H^9NH^2)^2H^2SO^4$, likewise forms colourless scales which dissolve with difficulty in cold, more readily in hot water. The *oxalate*, $(C^{12}H^9NH^2)^2H^2CO^4$, crystallises in long white needles which are soluble in water and in alcohol. The *nitrate*, $C^{12}H^9NH^2.HNO^3$, forms iridescent scales soluble in water. The *platinohydrochloride*, $2(C^{12}H^9NH^2.HCl).PtCl^4 + 2H^2O$, forms yellow glistening scales, moderately soluble in hot alcohol.

The properties of the base and of its salts show that it is identical with Hofmann's xenyamine (v. 1054).

Acetamidodiphenyl, $C^{12}H^9.C^6H^4.NH.COCH^3$, prepared by the action of glacial acetic acid on amidodiphenyl, forms long colourless needles which melt at 187° and dissolve easily in alcohol (Osten).

Dinitrodiphenyl, $C^{12}H^8(NO^2)^2$ (iv. 410), is not oxidised by heating it with acetic acid and chromic trioxide, but **amidonitrodiphenyl**, $C^{12}H^9(NO^2)(NH^2)$, is thereby

converted into *paranitrobenzoic acid*. When this amido-compound is converted into *bromonitrodiphenyl* by means of the diazo-reaction, and the latter is oxidised, it yields *paranitro- and parabromobenzoic acid*. The same *bromonitrodiphenyl* is obtained, together with another compound, probably an isomeride, by nitrating *monobromodiphenyl*; it is almost insoluble in cold alcohol, sparingly in hot alcohol, and crystallises from toluene in colourless needles melting at 173° and boiling above 360° . From this it appears that *dinitrodiphenyl* is a *dipara-compound*, and this is further proved by the fact that by converting *benzidine* into *dibromodiphenyl*, a compound is obtained which is identical with common *dibromodiphenyl*, both yielding by oxidation *parabromobenzoic acid*. When *Fittig's isodinitrodiphenyl* (iv. 410) is reduced with hydrogen sulphide, *isocamidonitrodiphenyl* is produced, crystallising from alcohol in short red prisms which melt at 92° - 93° . It differs from the *para-compound* by forming crystallisable salts. The *hydrochloride*, $C^{12}H^{10}(NO^2)(NH^2).HCl$, crystallises in long white needles which may be dried at 100° , and decompose only when washed with a large quantity of water (Schultz).

Tetranitrodiphenyl, $C^{12}H^4(NO^2)_4$, is formed by dissolving *dinitrodiphenyl* in fuming nitric acid, or by acting on *diphenyl* with a large excess of a mixture of equal volumes of strong nitric and sulphuric acids. On adding water to the solution the *tetranitrodiphenyl* separates as an amorphous mass, which dissolves sparingly in alcohol and more readily in ether, from which solvent it separates as a friable amorphous mass melting at 140° . By ammonium sulphide, or by tin and hydrochloric acid, it is reduced to a mixture of amido-compounds which have not yet been separated (Lasantsch, *Deut. Chem. Ges. Ber.* iv. 404).

Oxydiphenyl, Hydroxyldiphenyl, Diphenylic Phenol, or Diphenol, $C^{12}H^{10}O = C^{12}H^8OH = C^6H^5-C^6H^5OH$. This compound is formed by heating potassium diphenylsulphonate, $C^{12}H^8SO^2K$, with potassium hydrate (Latschinoff, *Deut. Chem. Ges. Ber.* vi. 194), or by the action of potassium nitrite on monamidodiphenylsulphonate (Osten, *ibid.* vii. 170). It crystallises in colourless glistening plates, volatilises with vapour of water, sublimes easily, and gives a fine green colour with strong sulphuric acid (Osten). It dissolves readily in alcohol of 40 p.c., in ether, and in caustic potash; gives no coloration with ferric chloride; is not attacked by ammoniacal silver nitrate even at the boiling heat; gives with lead acetate a precipitate soluble in acetic acid (Latschinoff).

Nitric acid converts it mono- and dinitro-oxydiphenyl, the former of which melts at 67° and volatilises with vapour of water, while the latter melts at 154° and does not volatilise with vapour of water (Latschinoff).

With *benzoyl chloride* oxydiphenyl forms *benzoyl-oxydiphenyl*, $C^{18}H^{14}O^2 = C^{12}H^8OC^6H^5O$, which melts at 132° and dissolves with difficulty in alcohol and in ether (Latschinoff).

Diphenylsulphonic Acids (Engelhardt & Latschinoff, *Deut. Chem. Ges. Ber.* ix. 561; Latschinoff, *ibid.* vi. 193). *Diphenyl* heated with sulphuric acid yields two sulpho-acids which may be partially separated by their potassium salts, the monosulphonate being the less soluble in water of the two, but more completely by means of their copper salts, the disulphonate being but slightly soluble even in boiling water.

Potassium diphenylmonosulphonate, $C^{12}H^8SO^2K + H^2O$, prepared from the copper salt, crystallises from alcohol of 40 p.c. in flat needles or long plates moderately soluble in water, easily in dilute alcohol. The *copper salt*, $(C^{12}H^8SO^2)_2Cu + 6H^2O$, crystallises in rhombs or prisms sparingly soluble in water, more easily in alcohol of 40 p.c. In absolute alcohol all the diphenylmonosulphonates dissolve but sparingly. The *barium and calcium* salts obtained by precipitation from the potassium salt are anhydrous.

Diphenyl-disulphonic acid, $C^{12}H^4(SO^2H)^2$, is the chief product obtained when *diphenyl* is heated with excess of sulphuric acid, and its salts are produced together with a sublimate of *diphenyl*, by the action of heat on the diphenylmonosulphonates, e.g.—

The *potassium salt* crystallises in thick laminae containing $2\frac{1}{2}H^2O$. Its solution is precipitated by barium chloride in the cold, by calcium chloride when heated.

By distilling the disulpho-acid with potassium cyanide, and boiling the residue with potash, a dicarbonic acid, $C^{12}H^4(CO^2H)^2$, is obtained.

Diphenyl-disulphonic acid or its potassium salt,* fused with potash, yields first the

* In the report of Latschinoff's paper (read before the Russian Chemical Society) in the *Berichte der Deutschen Chemischen Gesellschaft*, vi. 194, the salt concerned in this reaction is called "monodiphenylsulfonates Kalium," whereas it is clearly the disulphodiphenate; and on p. 195 of the same report the oxydiphenylmonosulphonate, $C^{12}H^8(SO^2K)OH$, is called "Mononitrodiphenylsulfonates Kalium."

potassium salt of oxydiphenylmonosulphonic acid, and then diphenol—

Oxydiphenylsulphonic Acids. Oxydiphenyl cautiously heated with sulphuric acid yields a mixture of mono- and disulphonic acid, $\text{C}^{12}\text{H}_8(\text{SO}^3\text{H})(\text{OH})$, and $\text{C}^{12}\text{H}_8(\text{SO}^3\text{H})_2\text{OH}$, which may be separated by means of their potassium salts, the mono-salts being less soluble than the corresponding di-salts. Ferric chloride gives no colour with the mono-salts, but a characteristic indigo colour with the di-salts. The mono-acid and its salts are converted by further heating with sulphuric acid into the di-salts.

Potassium Oxydiphenylmonosulphonate. $\text{C}^{12}\text{H}_8(\text{SO}^3\text{K})(\text{OH}) + \text{H}^2\text{O}$ or $\text{C}^{12}\text{H}_8\text{SO}^3\text{K} \cdot \text{C}^6\text{H}_5\text{OH} + \text{H}^2\text{O}$, dissolves easily in weak potash-ley, not however forming a basic salt; also in boiling water, sparingly in cold water, most easily in boiling alcohol of 40 p.c. By distillation it yields oxydiphenyl and potassium oxydiphenyl-disulphonate—

The barium, calcium, copper, and lead salts, are convertible into easily soluble basic salts; crystallise, some in laminæ, others in needles; dissolve sparingly in water and in alcohol; somewhat more readily in spirit of 40 p.c. The neutral barium salt contains $1\text{H}^2\text{O}$; the neutral calcium salt, $3\text{H}^2\text{O}$. The potassio-cupric salt, $[\text{C}^{12}\text{H}_8\text{SO}^3(\text{OH})]_2\text{K}^2\text{Cu} + 6\text{H}^2\text{O}$, crystallises in green laminæ.

Potassium Oxydiphenyl-disulphonate. $\text{C}^{12}\text{H}_8(\text{SO}^3\text{K})_2\text{OH} + 1\frac{1}{2}\text{H}^2\text{O}$ or $\text{C}^{12}\text{H}_8(\text{SO}^3\text{K})_2 \cdot \text{C}^6\text{H}_5\text{OH} + 1\frac{1}{2}\text{H}^2\text{O}$, obtained as above described, forms nodular groups of needles, easily soluble in water, precipitated from the solution by alcohol. Its solution forms no precipitate with barium, calcium, copper, or silver salts; with lead salts a scanty precipitate, probably of a basic salt, soluble in acetic acid. In presence of ammonia, basic salts are thrown down by solutions of barium, calcium, or lead salts.

PHENYL ETHER. See PHENYL OXIDE.

PHENYL KETONES (Kollarits a. Merz, *Deut. Chem. Ges. Ber.* v. 447; vi. 1035). *Diphenyl ketone* or *Benzophenone* (p. 176) is formed, together with a small quantity of a substance of high boiling point, by heating a mixture of benzene and benzoic acid with phosphorus pentoxide to 180° – 200° :

The benzoic acid in this process may be replaced by benzoic anhydride, and the phosphoric anhydride by metaphosphoric, and even by pyrophosphoric acid, the yield in the latter case being, however, but small. Boron trioxide and dry hydrochloric acid do not act on benzene and benzoic acid, even at 250° .

Chlorodiphenyl ketone, $\text{C}^{12}\text{H}_7\text{ClCO} \cdot \text{C}^6\text{H}_5$, is obtained in like manner from chlorobenzene. It crystallises from a mixture of ether and alcohol in flat needles resembling benzoic acid, and from petroleum-naphtha in needles grouped in globular masses, melting at 75.5° – 76° and boiling above 300° .

Bromodiphenyl ketone, $\text{C}^{12}\text{H}_7\text{BrCO} \cdot \text{C}^6\text{H}_5$, is obtained from bromobenzene, and has great resemblance to the preceding compound. It melts at 81.5° .

Dinitro-diphenyl ketone, $\text{C}^{12}\text{H}_7\text{NO}_2\text{CO} \cdot \text{C}^6\text{H}_4\text{NO}_2$, is formed by boiling dinitro-diphenylmethane with chromic acid solution; it is also obtained by the nitration of benzophenone, and is identical with that which Linnemann obtained by the action of nitric acid on benzhydrol. It crystallises from a mixture of alcohol and ether in small, shining needles, melting at 129.5° (W. H. Doer, *Deut. Chem. Ges. Ber.* v. 796).

Isonitro-diphenyl ketone is not produced in the nitration of benzophenone, but is formed by oxidising isodinitro-diphenylmethane. It is soluble in alcohol, ether, benzene, and acetic acid. From alcohol it crystallises in short straw-coloured needles or pale-yellow prisms; it melts at 118° (Doer).

Diamido-diphenyl ketone, identical with Laurent's and Chancel's *flavine* (ii. 656), forms long, pale-yellow needles, melting at 165° . The corresponding iso-compound could not be obtained in the pure state (Doer).

Tolyl-phenyl Ketone, $\text{C}^{11}\text{H}_7\text{CO} \cdot \text{C}^6\text{H}_5$, is obtained by heating toluene with benzoic acid and phosphorus pentoxide to 180° – 200° for 8–10 hours. It is first obtained as an acid liquid, from which, after some time, long pointed plates separate out, which crystallise from a mixture of ether and petroleum-naphtha in large thick prisms resembling celestine, and melting at 56.5° – 57° . It is readily soluble in ether and benzene, sparingly in petroleum-naphtha, and little more freely in alcohol. By oxidation with

chromic acid it yields benzoyl-benzoic acid, and therefore appears to be identical with Zincke's tolyl-phenyl ketone, although the latter compound is, according to this chemist, an oily liquid. When the solid ketone is heated with soda-lime to 260°-270°, it is resolved into benzene and paratoluic acid:

The portion of the ketone which remains liquid on standing yields also a large quantity of paratoluic acid; orthotoluic acid could not be detected.

Cynyl-phenyl Ketone, $\text{C}^{10}\text{H}^{12}\cdot\text{CO}\cdot\text{C}^6\text{H}^5$, is obtained in small quantity only, by heating camphor cymene with benzoic acid and phosphorus pentoxide. It is a pale yellow oil, having a very agreeable odour, and boiling at about 340°. It does not solidify in a freezing mixture, but becomes very viscid (Kollarits a. Merz).

α- and β-Naphthyl-phenyl Ketone, $\text{C}^{10}\text{H}^7\cdot\text{CO}\cdot\text{C}^6\text{H}^5$.—These two isomerides are formed together by heating naphthalene with benzoic acid and phosphorus pentoxide for 10-12 hours to 200°-220°. The α-compound crystallises from a mixture of ether and alcohol in thick short prisms melting at 77·5°; the β-compound forms needles melting at 82°. By separating the two kinds of crystals mechanically and recrystallising them, they may be obtained pure. When α-naphthoic acid is heated with benzene and phosphorus pentoxide, only a small quantity of the α-ketone is produced, besides carbon dioxide, naphthalene, and α-dinaphthyl ketone. The latter compound is a glassy mass, which by recrystallisation, first from a mixture of ether and alcohol, and then from alcohol alone, yields colourless pointed needles melting at 135° and distilling without decomposition. It is also produced by heating naphthalene with α-naphthoic acid and phosphorus pentoxide. β-naphthoic acid and benzene give a good yield of β-naphthyl-phenyl ketone. β-dinaphthyl ketone is formed by heating β-naphthoic acid with naphthalene and phosphorus pentoxide to 200°-220° for 20 hours. It crystallises from hot alcohol in plates, which soon separate into needles. It is less soluble in alcohol than the α-compound, and melts at 134·6°-135°. According to theory, three dinaphthyl ketones may exist. The third modification appears to be formed by distilling a mixture of potassium β-naphthalene-sulphonate and oxalate; it melts at 140° (Kollarits a. Merz).

Phenyl-methyl Ketone or Acetophenone, $\text{CH}^3\cdot\text{CO}\cdot\text{C}^6\text{H}^5$, forms two nitro-derivatives, one solid and the other liquid, the latter of which, when heated with soda-lime and zinc-dust, yields a small quantity of indigo-blue (p. 606).

When boiling acetophenone is treated with dry ammonia and the product is distilled, a thick oil passes over first, and then a crystalline substance partially soluble in hydrochloric acid. Ammonia added to this solution throws down a base called acetophenonine, $\text{C}^8\text{H}^{10}\text{N}$, or $\text{C}^8\text{H}^9\text{N}^2$, which crystallises from hot alcohol in fine, interlaced needles melting at 130°. It is a very stable compound, not being decomposed by red-hot soda-lime or by a boiling solution of chromic acid. It is not produced by heating acetophenone with alcoholic ammonia.

Acetophenonine hydrochloride forms small, thin plates, and is decomposed by water. *Nitro-acetophenonine*, $\text{C}^8\text{H}^{10}(\text{NO}^2)\text{N}$ [?], crystallises from hot ether in yellowish needles.

The portion of the product of the action of ammonia and phosphorus pentoxide on acetophenone, which is insoluble in acids, consists of triphenyl-benzene, $\text{C}^6\text{H}^5(\text{C}^6\text{H}^5)^3$ (p. 945), (Engler a. Heine, *Deut. Chem. Ges. Ber.* vi. 638).

Methyl-phenylmethyl Ketone, Benzyl-methyl Ketone, or Phenyl-acetone, $\text{CH}^3(\text{C}^6\text{H}^5)\cdot\text{CO}\cdot\text{CH}^3$, is produced, together with acetone, diphenyl-acetone, toluene, and an empyreumatic oil, by the dry distillation of a mixture of equal parts of acetate and phenyl-acetate (alpha-toluete) of barium:

The ketone, purified by fractional distillation, boils at 215°, and has a specific gravity of 1·010 at 3°. It unites with sodium bisulphite, forming a compound which may be crystallised from dilute alcohol. When it is heated with phosphorus pentachloride, and afterwards with alcoholic potash, a hydrocarbon appears to be formed (R. Otto, *J. pr. Chem.* [2], i. 144).

Diphenyl-methyl Ketone, Dibenzylic Ketone, or Diphenyl-acetone, $\text{CO} \begin{Bmatrix} \text{CH}^2(\text{C}^6\text{H}^5) \\ \text{CH}^2(\text{C}^6\text{H}^5) \end{Bmatrix}$, is formed by the dry distillation of barium phenylacetate. The distillate, which solidifies at low temperatures, may be purified by pressure and crystal-

lisation from alcohol. It forms transparent flattened prisms an inch long, melts at 30° and boils at 320°. The fused mass solidifies in stellate groups of long needles (Engler & Heine).

PHENYL OXIDE, $C^6H^5O = C^6H^5.O.C^6H^5$. This body, isomeric with oxydiphenyl, was first obtained by List & Limpricht by the dry distillation of cupric benzoate (iv. 417), and has been more completely examined by Hofmeister (*Deut. Chem. Ges. Ber.* iii. 747), who obtains it also by the action of diazobenzene sulphate on phenol. Aniline sulphate is rubbed to a paste with water; a rapid stream of nitrous acid is passed through it; the solution is mixed with phenol; the mixture, after standing for some time, is carefully heated till all the nitrogen has escaped, then treated with caustic soda; the undissolved portion is distilled with vapour of water, as long as an oil passes over, and this oil is purified by rectification. The reaction is as follows:

In preparing phenyl oxide by the process of List & Limpricht, Hofmeister mixes the crude distillate with soda-ley, and distils it over an oil-bath with addition of water.

Phenyl oxide is a colourless solid mass having an odour of geraniums; melting at 28° and boiling at 246°; nearly insoluble in water, easily soluble in alcohol, benzene, and glacial acetic acid, miscible with ether.

Phenyl oxide is not decomposed by passing over red-hot zinc-dust, or by heating with hydriodic acid. Heated to 220° for 10 hours with pentachloride and oxychloride of phosphorus, it yields a chlorinated oil boiling at 260°–280°. On agitating it with strong sulphuric acid, the chief product obtained is a disulphonic acid (*infra*); if, however, the phenyl oxide is not quite pure, diphenyl is at the same time produced.

Dibromophenyl oxide, $C^6H^4Br^2O$, produced by the action of bromine on phenyl oxide dissolved in carbon sulphide, dissolves easily in alcohol, ether, benzene, and glacial acetic acid, and crystallises from alcohol in long, colourless, shining needles melting at 53°–55°.

Dinitrophenyl oxide, $C^6H^4(NO^2)^2O$, produced by the action of fuming nitric acid on phenyl oxide, forms long silky needles which melt at 135° and dissolve easily in alcohol, ether, benzene, and glacial acetic acid.

Diamidophenyl oxide, $C^6H^4(NH^2)^2O$, formed by the action of tin and hydrochloric acid on the dinitro-compound, crystallises in nearly colourless scales which become dark-coloured on exposure to moist air, and melt at about 185°. The sulphate crystallises in fine needles.

Phenyl-oxide-disulphonic acid, $C^6H^5SO^2O = C^6H^5(SO^2H) - O - C^6H^5(SO^2H)$.—This acid, isomeric with oxydiphenyl-disulphonic acid (p. 939), is obtained by heating phenyl oxide with sulphuric acid, as a colourless syrupy liquid, which evaporated in the exsiccator, deposits large hard crystals, deliquescent in the air, easily soluble in alcohol, insoluble in ether. The **barium salt**, $\begin{matrix} C^6H^5SO^2 \\ C^6H^5SO^2 \end{matrix} BaO$ (dried at 120°) is a crystalline powder which dissolves slowly but abundantly in water; it contains water of crystallisation. The **sodium salt**, $(C^6H^5SO^2Na)^2O$, forms microscopic rhombic plates containing water of crystallisation. The **silver salt** crystallises in warty groups; the **lead salt** in slender needles (Hofmeister).

Phenyl-allyl Oxide, $C^6H^5.CO.C^3H^5$. See ALLYL ETHERS (p. 56).

Phenyl-benzyl Oxide, $C^6H^5.CO.C^6H^5$. See BENZYL ETHERS (p. 180).

PHENYL SULPHIDES. The **monosulphide**, $(C^6H^5)^2S$, passed several times through an iron tube filled with nails and heated to low redness, is converted, with separation of a large quantity of carbonaceous matter, into an isomeric compound, **paraphenyl sulphide**, which may be purified by distilling the crude product, cooling the distillate to a low temperature, and recrystallising the solid substance which separates out. It is insoluble in water, moderately soluble in carbon sulphide, ether, and benzene. By digestion with chromic acid mixture it is converted, analogously to phenyl sulphide, into **parasulphobenzide**, $C^6H^5SO^2$. This latter melts at 230°, and crystallises from hot alcohol in long, white, shining needles, soluble in benzene, ether, and carbon bisulphide. By hot concentrated sulphuric or nitric acid, it is not decomposed, but simply dissolved (Stenhouse, *Proc. Roy. Soc.* xviii. 542).

Phenyl bisulphide, $(C^6H^5)^2S^2$, is formed: a. By the action of cyanogen chloride on the sodium salt of thiophenol (sodium phenyl-mercaptide):

(Clamm, *J. pr. Chem.* [2], i. 147).

B. By subjecting the mercury-compound of thiophenol (C^6H^5) 2 Hg to dry distillation or heating it with water to 180° , whereby it is resolved into mercury and phenyl bisulphide. This compound forms small white shining needles, which melt at 60° , and are converted by zinc and hydrochloric acid into thiophenol (Dreher & Otto, *Ann. Chem. Pharm.* cliv. 178).

PHENYLAMINES. 1. **Monophenylamine. Aniline, $C^6H^5.NH^2$.** *Solidifying point.* According to E. Lucius (*Deut. Chem. Ges. Ber.* v. 154), whose results are confirmed by Hofmann, aniline solidifies and remelts at -8° , not at -20° as commonly stated.

Combinations.—**a.** With Metallic Iodides.—On mixing alcoholic solutions of aniline and zinc iodide, the compound $2C^6H^5.N.ZnI^2$ is formed, as a crystalline magma which dissolves at the boiling heat; and the solution on cooling deposits the compound in strongly lustrous, colourless prisms and needles, which dissolve readily in alcohol, but are partially decomposed by solution in water. It is decomposed by heat, giving off aniline and afterwards vapours of iodine. The cadmium-compound, $2C^6H^5.N.CdI^2$, prepared in like manner, forms long brilliant needles. The mercury-compound, $2C^6H^5.N.HgI^2$, is prepared by dissolving mercuric iodide in a boiling solution of aniline, and separates on cooling in sulphur-yellow plates and prisms. It cannot be purified by recrystallisation from alcohol, since it decomposes immediately on solution, with separation of a bright vermilion-coloured crystalline precipitate. The yellow salt is insoluble in water, easily soluble in aniline and in alcohol containing aniline. When exposed to the air it gives off aniline and acquires a vermilion colour. When carefully melted in a test-tube it solidifies on cooling to a crystalline mass, exhibiting on isolated spots beautiful vermilion-coloured crystalline vegetations (H. Vohl, *Arch. Pharm.* [2], cxlviii. 201).

B. With Organic Acids.—Aniline mucate, $C^6H^5.O^2(C^6H^5.N)^2$, is formed by boiling mucic acid with water and aniline: also together with phenyl-mucamide, $C^6H^5.O^2(NHC^6H^5)^2$, by heating mucic acid with excess of aniline (p. 948). It forms faintly yellow crystals, which dissolve in water and lose aniline on prolonged heating therewith, apparently without forming an acid salt. It is insoluble in boiling alcohol, but gives off the whole of its aniline on prolonged treatment with the boiling liquid. When heated with alkalis it yields alkaline mucates and free aniline. Heated in an air-bath it loses water, and is converted into phenylmucamide:

By dry distillation it is resolved into aniline, water, carbon dioxide, and phenylpyrrol (Kötnitz, *J. pr. Chem.* [2], vi. 136).

Aniline saccharate forms a syrupy mass yielding by dry distillation an oil which solidifies to a crystalline mass, and is obtained in white laminae by recrystallisation from alcohol (Kötnitz, *Chem. Centr.* 1870, 143).

Reactions.—1. Aniline vapour passed over heated lead oxide yields a small quantity of a base which crystallises in needles and melts at 70° (Behr & van Dorp, *Deut. Chem. Ges. Ber.* vi. 755).

2. Commercial aniline heated with phosphorus and a little water, yields aniline-red, hydrogen phosphide being formed and the aniline being oxidised by the liberated oxygen (A. Stiasny, *Dingl. polyt. J.* xcix. 413).

3. When aniline in excess is boiled with sulphur as long as hydrogen sulphide continues to be evolved, thioaniline, $C^6H^5.N^2S = S(C^6H^5.NH^2)^2$, is formed, together with a large quantity of resinous matter, probably containing more highly sulphuretted anilines (Morz & a. Weith, *Deut. Chem. Ges. Ber.* iii. 978).

4. When aniline is treated with pure sulphur chloride, S^2Cl^2 , diluted with carbon bisulphide, a reaction takes place in two stages, in the first of which, phenylsulphocarbamide (sulphocarbaniide), aniline hydrochloride, and free sulphur are formed, according to the equation:

and in the second, the excess of sulphur chloride acts on the sulphocarbaniide in such a manner as to produce triphenyl-guanidine and phenyl-sulphocarbimide:

This last reaction is exactly similar to that which was observed by Hofmann (1st Suppl. 686) to take place between sulphocarbaniide and iodine (Claus & Krall, *Deut. Chem. Ges. Ber.* iv. 147).

5. Aniline acetate, dissolved in acetic acid, is violently attacked by chromic oxychloride, and the product, diluted with water, yields on distillation a very turbid yellow distillate, from which needle-shaped crystals separate; these, however, disappear

after a while, and the solution then no longer contains any crystallisable compound (Carstanjen, *J. pr. Chem.* [2], ii. 82).

6. With *cyanogen*, aniline forms, together with aniline cyanide, a red crystalline mass which, when purified, yields fine red crystals of a mono-acid base, having the formula $C^6H^5N^3$, and forming with hydrochloric acid the crystalline salt $C^6H^5N^3.HCl$. This body may be regarded as triphenyl-guanidine cyanide, and represented by the formula $N^3[C^6H^4(C^6H^5)^3].2CN$. When heated with weak spirit (bost under pressure) this base is resolved into diphenylparabanic acid, ammonia, and aniline:

On boiling the alcoholic solution of the base with concentrated hydrochloric acid for some time, the diphenylparabanic is also decomposed, and ultimately ammonia, aniline, carbon dioxide, and oxalic acid are produced (Hofmann, *Deut. Chem. Ges. Ber.* iii. 763).

7. With *carbon tetrabromide*, aniline forms hydrobromide of triphenyl-guanidine (Bolas a. Groves, p. 257):

8. Aniline, added by small quantities to *chloracetyl chloride*, which must be kept cool, forms phenyl-chloracetamide, which crystallises from aqueous solution in slender needles and from alcohol in plates:

(Tommasi, *Compt. rend.* lxvi. 885).

9. Aniline, heated to 150° – 170° with *ethylidene-chloride*, forms diethylidene-diphenyl-diamine (also produced by the action of aldehyde on aniline, iv. 456):

(H. Schiff, *Deut. Chem. Ges. Ber.* iii. 412).

10. With *chloral*, aniline appears to form basic compounds (Wallach, *ibid.* iv. 668); see also Maumené (*Bull. Soc. Chim.* [2], xiii. 409).

11. Aniline containing potassium in solution forms, with *bromobenzene*, a comparatively small quantity of diphenylamine, and a larger quantity of triphenylamine (Merz a. Weith, *Deut. Chem. Ges. Ber.* v. 646).

12. When aniline hydrochloride is heated to 230° – 250° for several hours with *methyl alcohol*, a yellow transparent honey-like mass is formed, consisting chiefly of methylaniline hydrochloride:

and on heating the contents of the tube for a day, this mass is converted by intramolecular transposition into the crystalline hydrochloride of toluidine (Hofmann, *ibid.* v. 720):

13. A mixture of aniline, aniline hydrochloride, and *furfural*, all in alcoholic solution, solidifies to crystals of the hydrochloride of furfuraniline, $C^6H^5O.N^3.HCl$. Other salts of this base are obtained in like manner. The base itself, separated by triturating its salts with ammonia and kneading with water, forms a brown mass. Its alcoholic solution decomposes in contact with the air, and then no longer forms crystallisable salts with acids (Stenhouse, *Proc. Roy. Soc.* xviii. 537).

14. With *nitrobenzoic aldehyde*, aniline forms nitrobenzenylanilide,* $C^6H^5N^3O$:

An isomeric compound, benzenyl-nitranilide, is formed by the action of benzoic aldehyde on nitraniline:

* Called, in the original paper, *nitrobenzoylanilide*

Nitrobenzoic aldehyde and nitraniline yield nitrobenzyl-nitranilide, $C^6H^4N^2O^4$:

Lazorenco (*N. Petersb. Acad. Bull.* xv. 372).

Bromaniline, $NH^2(C^6H^4Br)$, (Fittig & Mager, *Deut. Chem. Ges. Ber.* vii. 1175). *Parabromaniline* was prepared from the nitrobromobenzene obtained by nitration of metabromobenzene, by reduction with tin and hydrochloric acid, and distillation of the solution mixed with caustic soda. When purified by crystallisation from aqueous alcohol, it forms large colourless regular octohedrons, melting at 63° , decomposed by distillation. The monobromophenol obtained from this bromaniline by the diazo-reaction melts at 63° – 64° , boils at 238° , and is converted by fusion with potash into resorcin.

Orthobromaniline, obtained in like manner by nitration of orthobromobenzene, &c., melts at 31° – 31.5° , boils at 229° , and distils without decomposition.

Chloraniline, $NH^2(C^6H^4Cl)$. An alcoholic solution of this base, heated with carbon sulphide, yields a sulphurea, $CS(NH.C^6H^4Cl)^2$, which crystallises from alcohol in long white needles, melting at 166° (Losanitsch, *ibid.* v. 156).

Nitraniline, $NH^2(C^6H^4NO^2)$. Of the three possible modifications of this base, two have long been known, viz.: orthonitraniline (1 : 2) from acetanilide, and metanitraniline (1 : 3) from dinitrobenzene (p. 925).* The third, or paranitraniline (1 : 4), has lately been obtained by Walker & Zincke (*ibid.* v. 114), by heating paranitrobenzene (p. 142) to 180° – 190° with concentrated alcoholic ammonia, then evaporating to dryness, and recrystallising from water.

Paranitraniline is distinguished from the other two modifications by its melting point, solubility, and the colour of its salts. It is much more soluble than the ortho- and meta-modifications in water and in alcohol; its solutions are intensely yellow, and communicate this colour to the skin. It volatilises more easily with vapour of water, and the watery distillate has a strong yellow colour. The melting points of the three nitranilines are as follows:

	Ortho- 146°	Meta- 108°	Para- 66°
--	----------------	---------------	--------------

Paranitraniline, heated between two watch-glasses, yields a sublimate of oily drops which become crystalline. Like the other two nitranilines, it forms unstable salts which, however, are not colourless, but distinctly yellow.

Diphenylamine, $C^6H^5N = NH(C^6H^5)^2$. According to Dusart & Bury (*Compt. rend.* lxxiii. 1276), this base is produced by the action of various phenol-compounds on aniline, the reaction consisting in the substitution of phenyl derived from the phenolic ether for an atom of hydrogen in the aniline molecule; thus—*a.* By heating aniline to 225° with dry sodium phenylsulphonate. *B.* By heating a mixture of 1 pt. aniline hydrochloride, 2 pts. phenol, and 1 pt. fuming hydrochloric acid to 250° ; in the absence of the acid the reaction takes place only at 300° , showing that the acid acts as an etherifying agent. *γ.* By passing aniline and phenyl bromide (bromobenzene) through a tube heated to low redness, or by the action of sodium on the same mixture at ordinary temperatures; also by heating aniline to 180° with phenyl iodide. Girard & De Laira on the other hand (*Compt. rend.* lxxiv. 811, 1264), find that diphenylamine is not produced by heating dry sodium phenylsulphonate with aniline, unless a small quantity of an aniline salt is also present, in which case its formation is due to the action of the aniline salt on the aniline itself. Similarly the formation of diphenylamine on phenyl bromide or iodide occurs only when this iodide or bromide contains free acid, or when the aniline contains an aniline salt. Lastly Girard & De Laira were unable to obtain diphenylamine by heating aniline with phenyl chloride. They therefore conclude that diphenylamine is not produced by the substitution of a phenolic residue for an atom of hydrogen in aniline. See, on the contrary, Merz & Weith, *infra*.

According to Merz & Weith (*Deut. Chem. Ges. Ber.* v. 288) commercial diphenylamine is pure, with the exception of traces of aniline; it crystallises from ligroin in large plates, like naphthalene, and melts at 54° .

It is slowly acted upon by concentrated sulphuric acid at 150° – 160° , and converted into a mixture of *diphenylamine-monosulphonic* and *-disulphonic acids*, which may be separated by fractional crystallisation of the barium salts, since the salt of the monosulpho-acid is difficultly soluble, while that of the disulpho-acid is easily soluble in water. The action of oxidising agents on the solution of these sulpho-acids, or their salts, gives rise to a variety of characteristic colorations.

* Hitherto regarded as paranitraniline (p. 145), (inasmuch as the dinitrobenzene, lately shown to have its two nitro-groups in the relative positions (1 : 3), was formerly regarded as a *para*-compound (see p. 928).

Acetyldiphenylamine, $N(C^6H^5)_2C^2H^3O$, is obtained by the action of acetyl chloride on diphenylamine.

Carbon disulphide has no action on diphenylamine.

Chlorocarbonic ether and diphenylamine give the compound, $N(C^6H^5)_2.COOCCl^2H^3$.

Diphenylamine as a test for Nitrous and Nitric acids.—The reagent is prepared by pouring pure sulphuric acid over a few crystals of diphenylamine, and adding a little water, whereby the temperature is somewhat raised and the crystals are dissolved; the solution is then mixed with a larger quantity of pure acid. This clear colourless liquid at once produces a beautiful and very permanent blue coloration in ordinary sulphuric acid of 60° or 66° B., or in chamber acid (52° B.), containing even traces of nitrous acid. The reaction is at least as delicate as that with ferrous sulphate.

The test may be rendered quantitative by comparing the coloration produced respectively by 1 c.c. of the acid to be tested, and 1 c.c. of acid containing a known amount of nitrous acid with an excess of the reagent (a solution of 1 gram diphenylamine in 1 litre of pure sulphuric acid), and adding pure sulphuric acid to one or other of the solutions until the intensity of colour is alike in both cases. Although not absolutely accurate, the method is sufficiently so for most technical purposes, and is far simpler than many of the methods ordinarily employed (E. Kopp, *Deut. Chem. Ges. Ber.* v. 284).

Triphenylamine, $C^{18}H^{15}N = N(C^6H^5)_3$, is produced, together with a comparatively small quantity of diphenylamine, by the action of bromobenzene on aniline. It is sparingly soluble in alcohol, more readily in petroleum-naphtha, and crystallises in large thick plates, melting at 126° – 127° , and boiling at a high temperature. With different reagents it gives blue or green colours. Triphenylamine may also be obtained by the same reaction from diphenylamine (Merz a. Weith, *ibid.* v. 646).

PHENYL-BENZENES. *Diphenyl-benzene*, $C^{18}H^{14} = C^6H^4(C^6H^5)_2$, is formed, together with diphenyl and large quantities of yellow brominated products, by the action of sodium on an ethereal solution of solid dibromobenzene, or better of a mixture of this compound with monobromobenzene. To obtain it pure, the ethereal solution is mixed with water; the diphenyl distilled off; and the crystalline residue dried, distilled in a stream of carbonic anhydride, pressed between paper, and recrystallised from ligroin and benzene.

Diphenyl-benzene melts at 201° (corr. 205°), sublimes readily, and boils in the vapour of boiling sulphur (440°). It is insoluble in boiling alcohol, nearly insoluble in ether, somewhat more soluble in ligroin, and still more in benzene. From the latter solvent it crystallises in tufts of flat needles. It does not combine with picric acid (F. Riese, *Zeitschrift f. Chem.* [2], vi. 102, 735).

Triphenyl-benzene, $C^{24}H^{18} = C^6H^3(C^6H^5)_3$, is formed by the action of phosphorus pentoxide on acetophenone, in the same manner as mesitylene (trimethyl-benzene) from acetone:

also, together with acetophenone, by the action of dry ammonia and phosphorus pentoxide on boiling acetophenone; in this case it constitutes the portion of the product which is insoluble in acids (p. 940).

Triphenyl-benzene crystallises from ether in short, well-defined prisms melting at 167° – 168° . It is but slowly attacked by oxidising agents. With bromine and nitric acid it forms substitution-products (Engler a. Heine, *Deut. Chem. Ges. Ber.* vi. 838).

PHENYL-BIURETS. See BIURET (p. 193).

PHENYL-BROWN. This colouring matter, which possesses explosive properties, is formed by the action of strong nitric and sulphuric acid on phenol. From the experiments of Bolley a. Hammett (*Dingl. pol. J.* cxv. 150), it appears to be a mixture of dinitrophenol with a brown amorphous substance, which may be dissolved out by alkalis and precipitated by alcohol, and is not at all explosive. The explosive character of the phenyl-brown is therefore due to the dinitrophenol.

PHENYL-BUTYLENE, $C^{14}H^{12} = C^6H^3(C^6H^5)_2$ (Aronheim, *Deut. Chem. Ges. Ber.* v. 1068). This hydrocarbon is formed by mixing benzyl chloride with allyl iodide in ethereal solution, the action commencing at ordinary temperatures, but requiring the heat of the water-bath for its completion. The liquid portion of the product, fractionated in Linnemann's apparatus (p. 436), yields, first diallyl, and then phenyl-butylene passing over between 176° and 178° , the residue in the retort consisting chiefly of dibenzyl.

Phenyl-butylene is a colourless aromatic oil having an odour like that of unsaturated hydrocarbons, and a specific gravity of 0.915 at 15.5° . The direct action of bromine on it gives rise to the separation of hydrobromic acid, but on adding bromine to its

946 PHENYL-URETHANES—PHENYLENE-DIAMINE.

solution in chloroform, combination takes place, producing the bromide $C^6H^4Br^2$, in the form of an oil which distills without change. On treating this bromide with potash, hydrogen bromide is separated; but the formation of the hydrocarbon, C^6H^4 , has not been definitely established. By oxidation with dilute nitric acid phenyl-butylene yields an oil which smells like bitter almond oil, and a sublimate apparently consisting of benzoic and cinnamic acids.

PHENYL-CARBAMIC ETHERS, or PHENYL-URETHANES. On *Ethyl Phenylcarbamate* or *Carbanilate*, $CO \begin{Bmatrix} NH.C^6H^5 \\ OC^2H^5 \end{Bmatrix}$, see **CARBAMATES** (p. 252).

Isobutyl Phenylcarbamate, $CO \begin{Bmatrix} NH.C^6H^5 \\ OC^4H^9 \end{Bmatrix}$, is produced by mixing ethereal solutions of isobutyl chlorocarbamate and anilino. It crystallises in soft white needles, melting at 80° and boiling at 216° , a small portion being thereby resolved into isobutyl alcohol and phenyl-cyanate. It dissolves easily in alcohol and ether, sparingly in water (E. Mylius, *Deut. Chem. Ges. Ber.* v. 972).

PHENYL-DIACETAMIDE, $N(C^6H^5)(C^2H^3O)^2$, is formed by heating phenyl-sulphocarbimide with glacial acetic acid to 130° – 140° ;

It resembles acetamide, melts at 111° , and is resolved by alkalis into anilino and acetic acid (Hofmann, *Deut. Chem. Ges. Ber.* iii. 770).

DI-PHENYLENE KETONE, $CO \begin{Bmatrix} C^6H^5 \\ C^6H^5 \end{Bmatrix}$. On the formation and constitution of this hydrocarbon, and its conversion into phenylbenzoic acid, see pp. 94, 95, 435.

By distillation over *zinc-dust* , it is easily and completely reduced, forming a colourless hydrocarbon—doubtless diphenylene-methane, $CH^2 \begin{Bmatrix} C^6H^5 \\ C^6H^5 \end{Bmatrix}$ —which dissolves easily in alcohol, and crystallises in shining scales or warty concretions melting at 113° (Fittig, *ibid.* vi. 287).

DI-PHENYLENE OXIDE, $\begin{Bmatrix} C^6H^5 \\ C^6H^5 \end{Bmatrix} O$ (see p. 435).

PHENYLENE-DIAMINE. *Diamidobenzene*, $C^6H^4N^2 = C^6H^4(NH^2)^2 = N^2 \begin{Bmatrix} H^1 \\ (C^6H^4) \end{Bmatrix}$.—Two modifications (α and β) of this base were obtained by Hofmann, by the action of reducing agents on the corresponding nitramidobenzenes (nitranilines), $C^6H^4(NO^2)(NH^2)$ (see iv. 980; 1st. *Suppl.* 923). A third modification (γ) is obtained by the following processes:—
1. By distillation of either of the two diamidobenzoic acids produced from uramidobenzoic acid (1st *Suppl.* 923):

(Griess, *J. pr. Chem.* [2], iii. 143).

Now these two diamidobenzoic acids are derived from the same amidobenzoic acid (1 : 2), and their isomerism is explained by the following formula:

Consequently the phenylene-diamine formed from either of them will have the two groups NH^2 in contiguous places; that is to say, it will be an *ortho*-compound (1 : 2). Now β -phenylene-diamine (from dinitrobenzene) is known to be the *meta*-compound, and therefore α -phenylene-diamine must be the *para*-compound (1 : 4).

2. By boiling paradibromobenzene, $C^6Br^2HHBr^2HH$, with fuming nitric acid, treating the resulting nitrodibromobenzene (1 : 2 : 4) or $C^6Br(NO^2)HBr^2HH$, with alcoholic ammonia, whereby it is converted into nitramidobromobenzene (1 : 2 : 4), that is either $C^6(NH^2)(NO^2)HBr^2HH$, or $C^6Br(NO^2)H(NH^2)HH$; and reducing this last compound with tin and hydrochloric acid. The phenylene-diamine thus formed will have its two NH^2 groups in the position 1 : 2 or 1 : 3; but the identity of its properties

with those of Griess's base shows that it is the ortho-compound (Meyer a. Wurster, *Deut. Chem. Ges. Ber.* v. 362); compare p. 144.

3. By heating nitranilic acid with ammonia to 160°, whereby the group OCH^3 is replaced by NH^2 ; reducing the resulting nitroparamidobenzoic acid with tin and hydrochloric acid, and subjecting the diamidobenzoic acid thereby produced to dry distillation. Now since anilic acid is methyl-paraoxybenzoic acid, $\text{C}^6(\text{CO}^2\text{H})(\text{H})(\text{OCH}^3)\text{H}$, the nitroparamidobenzoic acid formed from it must have the constitution represented by one of the following formulæ:

Consequently the diamidobenzoic acid and the phenylene-diamine derived from it will have the two NH^2 -groups either contiguous (3 : 4 or 1 : 2) or separated by one interval (2 : 4 or 1 : 3). But this phenylene-diamine likewise agrees in properties with Griess's compound, and must therefore be regarded as the ortho-modification.

This conclusion is strengthened by the fact that when the nitroparamidobenzoic acid is treated with nitrous acid in alcoholic solution, it is converted, by substitution of H for NH^2 , into ordinary nitrobenzoic acid, $\text{C}^6\text{H}^4(\text{NO}^2).\text{CO}^2\text{H}$ (crystallising in needles which melt at 140°–141°, soluble in 400 pts. of water at 22.5°, yielding an ethylic ether which crystallises in plates melting at 40°–41°, and reduced by tin and hydrochloric acid to an amidobenzoic acid melting at 172°). Now since, in the formation of this acid from nitroparamidobenzoic acid, the NH^2 -group is replaced by H, whereas, in the conversion of the same acid into phenylene-diamine, it is the CO^2H -group that is thus replaced, it is clear that whether the nitroparamidobenzoic acid be represented by the first or the second of the above formulæ, 1 : 3 : 4 or 1 : 2 : 4, the phenylene-diamine and nitrobenzoic acid derived from it cannot have their side-chains in the same relative position. If the first be a 1 : 2 compound, the second must be 1 : 3, and vice versa. Now, according to recent investigations (p. 133), ordinary nitrobenzoic acid (like its congeners amidobenzoic, oxybenzoic acid, &c.) is a meta-compound, 1 : 3, and therefore the phenylene-diamine in question must be an ortho-compound, 1 : 2 (H. Salkowski, *Deut. Chem. Ges. Ber.* v. 722).

4. Orthophenylene-diamine is also produced by the action of tin and hydrochloric acid on the nitraniline obtained from the bromonitrobenzene which melts at 38°, which must therefore be likewise an ortho-compound (Zincke a. Sintenis, *ibid.* vi. 123).

Properties and Reactions.—Orthophenylene-diamine dissolves readily in hot water and crystallises therefrom in white, or often reddish, quadratic plates; it is also very soluble in alcohol and in ether.

The melting and boiling points of the three phenylene-diamines are shown in the following table:

	Melting point	Boiling point
Orthophenylene-diamine . . .	99°	252° (Griess)
Meta- or β -phenylene-diamine . . .	140	267 (Hofmann)
Para- or α -phenylene-diamine . . .	63	287 (Hofmann)

Orthophenylene-diamine sulphate, $\text{C}^6\text{H}^4(\text{NH}^2)^2.\text{SO}^4\text{H}^2 + 1\frac{1}{2}\text{H}_2\text{O}$, crystallises in shining scales easily soluble in hot, sparingly in cold water, and giving off their water of crystallisation at a few degrees above 100°. The *platinocliloride* is a brown-red precipitate.

On adding a concentrated solution of ferric chloride to a solution of this diamine in hydrochloric acid, ruby-red needles separate, consisting of the hydrochloride of a base, $\text{C}^6\text{H}^4\text{N}^4$, which may be obtained by adding ammonia to the solution of the hydrochloride, in deep yellow microscopic needles, almost insoluble in all neutral solvents. The formation of this base is perhaps represented by the equation $2\text{C}^6\text{H}^4\text{N}^2 + \text{O}^2 = 3\text{H}^2\text{O} + \text{C}^6\text{H}^4\text{N}^4$ (Griess).

According to Salkowski, orthophenylene-diamine, when oxidised by chromic acid mixture, gives off a strong odour of quinone; Meyer a. Wurster, on the other hand, did not observe this odour. Metaphenylene-diamine is known to yield quinone by oxidation; paraphenylene-diamine does not (iv. 481).

PHENYL-GUANIDINES. See GUANIDINE (p. 582).

PHENYL-METHANES. Diphenyl-methane or Benzyl-benzene, $\text{C}^6\text{H}^5(\text{CH}^2.\text{C}^6\text{H}^5)$, is formed, together with other products, by heating benzyl chloride with benzene and zinc-dust (Zincke, *Deut. Chem. Ges. Ber.* iv. 298), also by sulphuric acid diluted with glacial acetic acid, on a mixture of benzyl alcohol and benzene (Meyer a. Wurster, *ibid.* vi. 963). Respecting its properties, see BENZYL-BENZENE (p. 183). On its reaction with formaldehyde, see p. 535.

Substitution-derivatives of Diphenyl-methane (W. H. Doer, *Deut. Chem. Ges. Ber.* v. 795). **Dinitro-diphenylmethane**, $C^{12}H^{10}(NO^2)^2$, is produced by dissolving the hydrocarbon in cold fuming nitric acid of sp. gr. 1.5. It is insoluble in water and alcohol, sparingly soluble in ether, and crystallises from hot benzene in long, brittle, ridgescent needles, melting at 183° . By oxidation with chromic acid mixture, it is converted into dinitro-diphenyl ketone or dinitrobenzophenone (p. 939).

Isonitro-diphenylmethane, $C^{12}H^{10}(NO^2)^2$, is formed when diphenylmethane is heated in a water-bath with nitric acid of sp. gr. 1.4. It is insoluble in water, but soluble in alcohol, ether, benzene, and acetic acid, and crystallises in small straw-coloured needles, showing a blue lustre and melting at 172° . By oxidation it is converted into isodinitrobenzophenone.

Tetranitro-diphenylmethane, $C^{12}H^8(NO^2)^4$, is the chief product formed by the action of a well-cooled mixture of concentrated nitric and sulphuric acid on diphenylmethane. It is insoluble in water, alcohol, and ether, sparingly soluble in benzene, a little more in glacial acetic acid, from which it crystallises in brilliant, pale-yellow, hard prisms, melting at 172° .

Diamido-diphenylmethane, $C^{12}H^{10}(NH^2)^2$, crystallises from alcohol in small pearly scales, melting at 85° and having the greatest resemblance to benzidine. The hydrochloride is very soluble in water and alcohol, and crystallises from dilute hydrochloric acid in small white plates. The sulphate is sparingly soluble in alcohol, and crystallises from water in small brilliant plates.

Isonitro-diphenylmethane and its salts are very unstable compounds which could not be obtained in the pure state.

Diphenylmethane-disulphonic acid is formed by dissolving the hydrocarbon in an excess of fuming sulphuric acid on a water-bath. The potassium salt, $C^{12}H^{10}(SO^2K)^2 + H^2O$, crystallises from dilute alcohol in small shining prisms. The barium salt is anhydrous, and crystallises from an aqueous solution in very small scales. The copper salt, $C^{12}H^{10}(SO^2)^2Cu$, is soluble in water and crystallises from dilute alcohol in small, green shining plates. The free acid, $C^{12}H^{10}(SO^2H)^2$, separates from an aqueous solution in small deliquescent plates, and from alcohol in arborescent needles melting at 59° .

Bromine acts violently on diphenyl-methane, forming a viscid substance, which, after standing for months, yields crystalline crusts forming large tables when recrystallised from ether. This body contains 4 atoms of bromine, but the quantity obtained was not sufficient to decide whether it is an addition- or a substitution-product.

Triphenyl-methane, $CH(C^6H^5)^3$, is obtained by heating 1 mol. of benzylene dichloride with 2 mols. of mercury-diphenyl:

It is a solid, melting at 92.5° , and boiling at about 335° . From an alcoholic solution it separates in brilliant, well-formed crystals; it is also readily soluble in ether and benzene, forming with the latter hydrocarbon the compound $CH(C^6H^5)^3.C^6H^6$. This compound forms large transparent crystals, which melt at 76° , and at this temperature, or when exposed to the air, give off the benzene and become white and opaque. Triphenyl-methane is also soluble in toluene, but does not combine with it. On dissolving it in warm fuming sulphuric acid, it is converted into the sulphonic acid, $CH(C^6H^5)_3.SO^2H^2$, the barium salt of which is precipitated by alcohol from an aqueous solution in fine white needles. No other salt could be obtained crystallised, but a concentrated solution of the free acid solidifies on standing to a crystalline mass (Kekulé a. Franchimont, *Deut. Chem. Ges. Ber.* vi. 186).

PHENYL-MUCAMIDE, $C^6H^5O^2(NHC^6H^5)^2$ (Köttitz, *J. pr. Chem.* [2] vi. 136). This compound is formed, together with aniline mucate, by heating mucic acid with excess of aniline:

also by heating aniline mucate in an air-bath:

It is best prepared, however, by the action of aniline on an ether of mucic acid; ethyl mucate, for example.

Phenyl-mucamide forms small, very thin, white laminae, which are quite insoluble in water, alcohol, ether, benzene, carbon sulphide, glycerin, and dilute mineral acids. It is decomposed by boiling with strong potash, phenylamine being separated. Concentrated sulphuric acid converts it into a black mass. Fuming nitric acid dissolves it, forming a yellow solution, from which water throws down a yellow body, probably

a nitro-derivative. By dry distillation it yields phenyl-pyrrol, $N(C^6H^5)(C^6H^5)$. See PYRROL.

PHENYL-NAPHTHYLAMINE. See NAPHTHYLAMINE (p. 846).

PHENYL PURPURIC ACID. See PURPURIC ACID.

PHENYL-TRIESTEIDE, STANNIC, $Sn(C^6H^5)(C^6H^5)^3$. See STANNIC ETHIDES.

PHENYL-UREAS. See UREAS.

PHENYL-URETHANE, $CO \begin{cases} NH.C^6H^5 \\ OC^6H^5 \end{cases}$. See CARBAMATES (p. 252).

PHENYL-XYLIDINE, $NH(C^6H^5)(C^6H^5)$. See XYLIDINES.

PHLOROGLUCIN, $C^6H^5O^3$. This substance, treated with chlorine and water at ordinary temperatures, yields dichloroacetic acid (Hlasiwetz a. Habermann, *Ann. Ch. Pharm.* clv. 120).

PHOLERITE. A mineral from India named *Meerschaumite*, by Ross, has been recognised by Maskelyne a. Flight (*Chem. News*, xxii. 260) as pholerite, and found to consist of 43.144 p.c. SiO^2 , 41.073 Al^2O^3 and 17.783 water.

PHORONE, $C^6H^{10}O$ (Kachler, *Ann. Ch. Pharm.* clxiv. 76). This body, the ketone of camphoric acid, obtained by distilling the calcium salt of that acid, is likewise produced from acetone by the action of quicklime or of sodium, and by heating cane-sugar or grape-sugar with lime (i. 733). Schwanert's *camphrene*, obtained by the action of sulphuric acid on camphor, and supposed by him to be identical with phorone, appears to have been a mixture (p. 238).

Phorone from camphoric acid (b. p. 206° – 215°), oxidised with chromic acid mixture, yields acetic acid, and an acid isomeric with adipic acid, $C^6H^{10}O^4$, which, after the acetic acid has been distilled off, may be dissolved out of the residue by agitation with ether. The reaction takes place according to the equation:

Phorone prepared from cane-sugar yields the same products by oxidation with chromic acid. The acid, $C^6H^{10}O^4$, is likewise formed, together with oxalic acid, by oxidising phorone with nitric acid.

The relation of phorone to camphoric acid may be represented by the following formulæ (compare p. 234):

PHOSGENE. See CARBON OXYCHLORIDE (p. 261).

PHOSPHAMMITE. This name is given by C. U. Shepard to ammonium phosphate found in the guano of the Guanape islands, Peru (p. 584).

PHOSPHETHYL CYANIDE. See PHOSPHINES.

PHOSPHIDES, METALLIC. These compounds are formed in the decomposition by heat of certain hypophosphites (p. 966); also in some cases by the action of phosphorus on metallic solutions (p. 959).

Iron Phosphides.—*Triferrous phosphide*, Fe^3P^2 , is formed by pouring a solution of ferrous sulphate into a flask in which phosphoretted hydrogen is generated by heating phosphorus with potash-ley. The precipitate of ferrous hydrate produced in the first instance gradually turns grey, and finally black, by conversion into phosphide. The excess of phosphorus is removed by prolonged boiling with potash; the precipitate is boiled with strong hydrochloric acid to remove oxides and salts of iron; and the residual black powder is washed and dried in a stream of carbonic anhydride. As thus prepared it contains 71.74 to 72.17 p.c. iron and 28.48 to 27 phosphorus, agreeing approximately with the formula above given.

Triferrous phosphide dissolves very slowly in boiling hydrochloric acid alone; quickly, however, on addition of nitric acid. It is magnetic, and when recently prepared, takes fire in the air, even below 100° (Schenk, *Chem. Soc. J.* [2], xi. 826).

An octoferrous phosphide, Fe^8P^2 , is formed according to Sidot (*Compt. rend.* lxxiv.

1425), by heating iron-wire in vapour of phosphorus, and repeatedly igniting the product in a crucible. It forms a metallic mass having the appearance of pig-iron, and on breaking it, the interior is often found to be studded with beautiful crystals about half an inch long and having the form of square prisms. It has a steel-gray colour, and is iridescent on the surface; is nearly as hard as steel, and strongly magnetic.

Daubrée (*ibid.* 1427) observes that Boblique, some years ago, prepared a phosphide of iron on the large scale from the nodules of calcium phosphate which occur abundantly in the gault of the Ardennes, by smelting them in a blast-furnace with iron. The phosphide thus obtained resembled that just described in its metallic aspect and state of crystalline aggregation, and was also strongly magnetic; its crystalline form, however, was not determined.

According to C. Freese (*Deut. Chem. Ges. Ber.* v. 604) the method employed by Sidot does not yield a definite product, but a mixture of phosphides of variable composition.

Tetranickelous Phosphide, Ni_4P_2 , is best prepared by treating a nickel-solution with phosphoretted hydrogen in the manner above described. The black precipitate, purified in the same manner as the ferrous compound, gave by analysis (mean) 78.50 p.c. nickel and 20.50 phosphorus, the formula Ni_4P_2 requiring 79.19 Ni and 20.81 P. When precipitated nickel hydrate was used in the preparation, a partially oxidised product was obtained, the oxygen being apparently derived from water retained by the hydrate.

Tetranickelous phosphide is not magnetic. It dissolves slowly in dilute hydrochloric acid, quickly in dilute nitric acid; towards strong nitric acid it behaves like iron. In sulphuric acid, and in a mixture of nitric and hydrochloric acids, it dissolves sometimes slowly, sometimes quickly (Schenk, *Chem. Soc. J.* [2], xii. 214).

PHOSPHINES. *Phosphine or Gaseous Hydrogen Phosphide*, PH_3 .—The ordinary method of obtaining this gas by heating phosphorus with aqueous potash gives a mixture of phosphine with hydrogen, the amount of the former varying from 16 to 35 p.c. Better results are obtained with alcoholic potash, but the gas thus produced is still far from pure.

Calcium phosphide, treated with water, gives off a much purer gas, containing only about 13 p.c. of hydrogen; and when hydrochloric acid is substituted for the water, the evolved gas contains about 7 p.c. of hydrogen. The phosphoretted hydrogen obtained from crystallised phosphorous acid contains about 6 p.c. of hydrogen. Perfectly pure phosphine may, however, be obtained by the action of water, or, better, of potash, on the iodide of phosphonium.

This substance, in pieces about the size of peas, is placed in a flask provided with a delivery-tube, and with a bulb-tube having a stopcock passing through the cork in the usual manner. The bulb is filled with potash-solution of about the strength used in combustions, and when the gas is required a few drops are allowed to enter the tube. In this way the evolution can be easily stopped at any desired moment; 7.3 grams of phosphonium-iodide yield about a litre of gas. The gas thus obtained is perfectly pure if collected when free from air; it is entirely absorbed by a solution of chloride of lime; it is not spontaneously inflammable, although, on account of its purity, it is more easily ignited than the impure gas containing hydrogen, which has been deprived of its spontaneous inflammability. According to Rammelsberg, however (*Deut. Chem. Ges. Ber.* vi. 88), it sometimes takes fire spontaneously. When brought in contact with a drop of fuming nitric acid it takes fire, as it also does in contact with chlorine or bromine water; by passing the gas through nitric acid containing a trace of nitrous acid, it becomes spontaneously inflammable. On passing a series of electric sparks through the gas, it splits up into its components almost as easily as ammonia does (A. W. Hofmann, *ibid.* iv. 200).

The decomposition of phosphine is also effected, though not completely, by the silent electric discharge. The gas first becomes spontaneously inflammable, and then deposits the solid phosphide of hydrogen. After removing the undecomposed phosphine by absorption, the further action of the discharge splits up the solid phosphide into phosphine and red phosphorus. The latter, being a conductor, causes the silent discharge to change into the spark, and stops the action.

A mixture of phosphine and ethylene yields one of the phosphorus bases, various complicated secondary reactions going on at the same time (P. a. A. Thénard, *Compt. rend.* lxxvi. 1508).

Phosphine Hydriodide, or Phosphonium Iodide, PH_3HI or PH_4I .—This compound is now largely applied in the laboratory as a powerful reducing agent, and for the preparation of highly concentrated hydriodic acid, phosphoretted hydrogen,

and the alcoholic phosphines. The following method of preparing it in quantity is given by Hofmann (*Deut. Chem. Ges. Ber.* vi. 291):—

Phosphorus (400 grams) is dissolved in its own weight of carbon sulphide in a retort of 1 litre capacity, and to this solution, kept cool, iodine (680 grams) is added by small portions. The carbon sulphide is then carefully distilled off in a water-bath, an operation which takes 9 or 10 hours. The retort (fig. 25) is then connected with a long wide condensing-tube, and a two-necked globular receiver, from which a connecting tube passes to two condensing-bottles, the first containing weak hydriodic acid, the second water. Heat is then applied to the retort, gently at first, and water (240

Fig. 25.

grams) is slowly added through the drop-funnel. Phosphonium iodide and hydriodic acid are then produced, the latter passing off and collecting in the condensing-bottles, while the former sublimes and collects as a crust, chiefly in the tube, and in smaller quantity in the globular receiver, which, to prevent stoppage, should be connected with the long tube by a wide tube. To prevent the liquid in the condensing-bottles from being forced back, in consequence of the rapid absorption, a slow stream of carbonic acid gas is passed through the apparatus during the whole operation, the first condensing-bottle is charged with dilute hydriodic acid instead of with water, and the tubes connecting these bottles are blown out into bulbs of considerable diameter. A well-conducted sublimation may be completed in 8 or 9 hours. When it is finished, one end of the long condensing-tube is closed with a cork, and the phosphonium iodide, adhering in thick crusts to its inner surface, is detached by means of a stout wire bent and sharpened at the end. The hydriodic acid obtained as a by-product is moderately strong, but contains a little phosphoric acid.

Ethyl Phosphines. Hofmann (*Deut. Chem. Ges. Ber.* iv. 205) has obtained triethyl phosphine by the action of hydrogen phosphide on ethyl iodide under pressure. When phosphonium iodide (10 grams) is introduced into a strong glass tube within which is placed a narrower tube containing three times the quantity of ethyl iodide and a little water, and the sealed tube is heated in the horizontal position to 160° – 180° for several hours, triethyl-phosphine is formed, but in very small quantity. If, however, the tube be charged with 1 mol. phosphonium iodide and 3 mols. alcohol and heated to 180° , the contents solidify on cooling to a splendid snow-white crystalline mass consisting of nearly equal parts of the iodides of triethyl- and tetraethyl-phosphonium. The phosphonium iodide and the alcohol first form ethyl iodide and hydrogen phosphide, and these bodies react on one another in the manner just stated:

and—

A similar reaction takes place very easily with methyl alcohol. Allyl alcohol, phenol, and glycerin are also strongly attacked by the phosphonium iodide. This reaction does not yield primary or secondary phosphines.

Drechsel and Finkelstein (*ibid.* iv. 352) have obtained triethyl phosphonium iodide by the action of ethyl iodide on a zinc phosphide, probably ZnHP , prepared by passing dry hydrogen phosphide into a well-cooled ethereal solution of pure zinc-ethyl. This compound, which contains 17.80 p.c. phosphorus, is a white friable substance, small.

ing of hydrogen phosphide. Heated to 150° in a sealed tube with 5 pts. of ethyl iodide and excess of ether, it yields, together with zinc iodide, a compound of that body with the iodide of triethyl phosphonium, having the composition $\text{ZnI}^2 \cdot 2(\text{C}^2\text{H}^5)^3\text{HPI}$.

When a mixture of hydrogen phosphide and vapour of methyl iodide was passed over platinum sponge, no combination took place; but when iodide of ethyl or methyl saturated with the gas was left to itself for some time, or heated to 100° in sealed tubes, combination was effected. No phosphonium iodide was, however, produced, as the resulting crystals dissolved easily in water without evolution of gas: hence Drechsel and Finkelstein conclude that the iodide of monomethyl- or monethyl-phosphonium was formed by the above reaction. They also state that crystals of monomethyl-phosphonium iodide, $\text{PH}^3(\text{CH}^3)\text{I}$, are obtained by heating a mixture of 1 vol. methyl iodide with 1 vol. of a saturated ethereal solution of zinc iodide which has been saturated at -10° with hydrogen phosphide.

Hofmann (*ibid.*, iv. 372), on repeating the experiments of Drechsel and Finkelstein, finds that the reactions described by these chemists yield no primary or secondary but only tertiary phosphines; moreover that the primary and secondary bases are not formed by the action of alcohol on ethyl iodide in any proportions whatever. They are, however, easily produced by heating phosphonium iodide with ethyl iodide in presence of a metallic oxide, such as zinc oxide, the ordinary zinc-white of commerce answering the purpose very well. The best proportions are 1 mol. zinc oxide to 2 mols. phosphonium iodide and 2 mols. ethyl iodide. A mixture of 1 pt. by weight of zinc-white, 4 pts. phosphonium iodide and 4 pts. ethyl iodide is digested in sealed tubes at a temperature not exceeding 150° for 6 to 8 hours, by which time the tubes are found to be filled with a homogeneous, almost colourless, crystalline mass. A tube of about 60 c.c. capacity may be charged with 40 to 50 grams of the mixture. In filling the tube, it is best first to introduce the phosphonium iodide, then the zinc oxide, and finally the ethyl iodide; thus arranged these bodies do not react at ordinary temperatures, and the tubes may be sealed with safety.

The main product of the reaction is ethyl-phosphonium iodide, which unites with the zinc iodide to form a double salt:

Simultaneously, however, reaction takes place, but to a less extent, between 2 mols. ethyl iodide, 1 mol. phosphonium iodide, and 1 mol. zinc oxide:

with formation of diethyl phosphine, which combines directly with the zinc iodide. A small quantity of phosphonium iodide, therefore, always remains unacted upon. Together with these reactions, others take place, especially when the temperature has risen at all high, which give rise to the formation of permanent gases, perhaps ethylene or even marsh-gas. In these cases the product is no longer pure white, but has more or less of a reddish-yellow colour, in consequence of the separation of phosphorus iodide; the escaping gases then take fire only momentarily, whereas, when hydrogen phosphide is present, they burn for some minutes.

It is worthy of note that the reaction above described gives rise to the primary and secondary phosphines *only*; and since, as far as has been observed, the same appears to hold good in the methyl series, it follows that the reaction of phosphonium iodide on the iodides of the radicles is complementary to its action on the alcohols, in which case, as above stated, the tertiary and quaternary bodies only are formed.

The separation and purification of the two phosphines present in the product of the reaction is easily accomplished, and is based on the fact that the salts of the primary phosphines are perfectly decomposed by water, in the same manner as phosphonium iodide, with liberation of the phosphine and solution of the acid; whereas, the salts of the secondary phosphines withstand the action of even a large excess of boiling water, but are readily decomposed by alkalis. The operation is as follows:—The product from several tubes being placed in a suitable apparatus from which the air is expelled by a current of hydrogen, is acted on by a slow stream of water, which has been previously boiled and again cooled; the monethyl-phosphine is thus set free and condensed in a spiral surrounded by ice. As some quantity of the extremely volatile phosphine is liable to be carried away by the hydrogen, the gas is caused to pass, before its entry into the atmosphere, through a column of concentrated hydriodic acid. During the operation, this liquid becomes gradually filled with magnificent, dazzling white crystals of pure ethyl-phosphonium iodide. When, by the further addition of water, no more monethyl phosphine is evolved, even on warming, strong caustic soda-solution is added, the operation being still carried on in a current of hydrogen. The diethyl-phosphine then distils over readily on heating, and may be condensed in the ordinary manner.

The liquid thus obtained, after drying over potassium hydrate, is the chemically pure diethyl-phosphine.

Monethyl Phosphine, $P \begin{pmatrix} C^2H^5 \\ H \\ H \end{pmatrix}$, is a mobile, colourless, transparent liquid, boiling at 25° ; lighter than and insoluble in water; refracting light strongly, and entirely without action on vegetable colouring matters. It has a most overpowering odour, resembling that of the formonitrils; and, similarly, its vapour produces on the tongue an intensely bitter taste which extends far down the throat. Its fumes bleach cork, like chlorine; caoutchouc is affected by it in a remarkable manner, becoming transparent and losing its elasticity. In contact with chlorine, bromine, or fuming nitric acid, it takes fire. Sulphur and carbon bisulphide combine directly with it, but the resulting bodies are liquid, and not crystalline, like the corresponding triethyl-phosphine derivatives. Concentrated hydrochloric, hydrobromic, and hydriodic acid unite with it to form salts; the solution of the hydrochloride yields with platinum tetrachloride a double salt, crystallising in magnificent carmine-red needles, much resembling freshly prepared chromic anhydride. The *hydriodide*, $C^2H^5H^2P.HI$, forms white quadrilateral plates, which may be sublimed unchanged in a current of hydrogen at the temperature of boiling water; the crystals are permanent in dry air. It dissolves in water with complete decomposition; also in alcohol, but with partial decomposition; in ether it is insoluble; concentrated hydriodic acid is the only solvent which dissolves it, though sparingly, unchanged, the addition of ether causing the separation of the salt in large, well-formed plates, often a centimeter in diameter, but of extreme thinness.

Diethyl Phosphine, $P \begin{pmatrix} C^2H^5 \\ C^2H^5 \\ H \end{pmatrix}$, is a colourless, transparent, perfectly neutral liquid,

refracting light strongly, lighter than water, and insoluble therein. It boils constantly at 86° , or 60° higher than the primary base. It has a penetrating, persistent odour, different from that of monethyl phosphine, more resembling, although essentially different from, that of triethyl phosphine. It absorbs oxygen with great avidity, combination taking place with great energy, often causing it to take fire on opening the containing vessel. Diethyl phosphine combines both with sulphur and with carbon bisulphide to form liquids, a behaviour which affords a ready means of testing its freedom from admixture of triethyl phosphine. It dissolves easily in all acids, but none of its salts crystallise readily, except the hydriodide. The platinumchloride, which is easily alterable, crystallises in fine, large, orange-yellow prisms. The salts of diethyl phosphine are not decomposed by water.

Triethyl-phosphine oxide, $P(C^2H^5)_3O$.—Carius (*Ann. Ch. Pharm.* cxxxvii. 117) prepares this compound by acting upon ethyl iodide with phosphorus in sealed tubes at 160° , and heating the product to the same temperature with alcohol. Crafts & Silva (*Chem. Soc. J.* [2], ix. 629) modify this process as follows: 1 pt. of phosphorus is heated to 175° for 24 hours with 13 pts. ethyl iodide in sealed tubes laid horizontally; the crystals, coloured by iodine, which separate on cooling, are melted by gentle heating and transferred to a retort; the residual phosphorus cake (consisting chiefly of amorphous phosphorus) is pulverised, and likewise transferred to the retort; and the whole is boiled with alcohol of 97 p.c. as long as any ethyl iodide distils over. The concentrated solution then deposits white crystals, apparently consisting of compounds of triethyl-phosphine oxide and the hydrate, $P(C^2H^5)_3OH$, with iodine and the acids of phosphorus. On-distilling these crystals with 4 pts. of potassium hydrate, triethyl-phosphine oxide is obtained, towards the end of the operation, nearly in the pure state.

Carius represented the course of the reaction by which this product is obtained, by the following equation:

As, however, the product of the first stage of the reaction is nearly insoluble in water, whereas PI^3 and $P(C^2H^5)_3I$ are soluble, and moreover not merely the half, but four-fifths of the phosphorus is converted into triethyl-phosphine oxide, Crafts & Silva regard this view as erroneous, and suppose that the reaction represented by the first equation goes further, yielding, as final products, the iodides of triethyl phosphine and tetraethyl-phosphonium, together with free iodine; thus:

In the subsequent decomposition by alcohol and by potash, the greater part of the triethyl-phosphine oxide is produced from the corresponding iodide, inasmuch as the quantity of gas evolved in this reaction is comparatively small:

Triethyl-phosphine oxide boils at $242^\circ\text{--}243^\circ$ (uncorr.), and crystallises at 51.9° . It is very hygroscopic; traces of water lower its boiling and solidifying points very considerably. It is but slightly volatile with vapour of water. The oxygen in it is very intimately combined, not being either removable or replaceable by sulphur (acting as H^2S). It likewise offers great resistance to the action of chlorine, no perceptible reaction or formation of hydrochloric acid taking place below $180^\circ\text{--}200^\circ$, and the product then formed being decomposed by distillation. Heated to 190° for 4 hours with bromine and a little water, it yields a product which may be distilled, without decomposition, in a vacuum. Hydrochloric acid gas acts upon the oxide with the aid of heat, forming (amongst other compounds containing hydrochloric acid) a substance having nearly the composition $\text{P}(\text{C}^2\text{H}^5)_3\text{O.HCl}$. This compound forms silky needles like sulphuric anhydride, and solidifies after fusion at 127.5° . By heating the oxide in tubes with hydrobromic acid, a product was obtained which, under a pressure of 2 inches of mercury, boiled almost constantly at $205^\circ\text{--}210^\circ$. It contained only 32.17 p.c. bromine, whereas the formula $\text{P}(\text{C}^2\text{H}^5)_3\text{O.HBr}$ requires 37.21 p.c. After repeated distillation it contained still less bromine. Neither was any product of definite composition obtained by saturation of the anhydrous oxide with hydrobromic acid at 150° (Friedel & Crafts).

Methyl Phosphines (Hofmann, *Deut. Chem. Ges. Ber.* iv. 605). These compounds are formed in the same way as the corresponding ethyl-compounds, by heating in closed tubes 2 mols. phosphonium iodide, 2 mols. methyl iodide, and 1 mol. zinc oxide. A solid crystalline mass is thereby obtained, from which the phosphines are isolated by a method similar to that used for the preparation of the ethyl-compounds. The methyl phosphine, which escapes as a gas on adding water to the product of the reaction, is condensed in a flask surrounded by a mixture of ice and calcium chloride. The residue in the flask, which towards the end of the operation has to be heated in order to drive out all the monophosphine, solidifies, on cooling, to a mass of large, beautiful, perfectly white needles, a compound of dimethyl-phosphonium iodide with zinc iodide, from which the base is liberated by adding a solution of caustic soda; it is condensed in a vessel surrounded by ice-water.

Methyl Phosphine, $\text{PH}^2(\text{CH}^3)$, is a colourless transparent gas, having even a more overpowering smell than ethyl phosphine. By cold or pressure it may be condensed into a liquid lighter than water, which boils at -14° . It is insoluble in water, sparingly soluble in ether, more freely in alcohol. In contact with air it fumes, being gradually oxidised, but takes fire when gently heated or when brought in contact with chlorine, bromine, or nitric acid. With acids it forms well-defined salts, which are all decomposed by water, and have the remarkable property of bleaching vegetable colours like chlorine. On holding in the gas a strip of litmus-paper partially moistened with water and partly with an acid, only the latter portion is bleached, showing that the free base itself has not this property.

The hydrochloride, $\text{P}(\text{CH}^3)_2\text{H}^2.\text{ClH}$, is obtained by mixing equal volumes of hydrochloric acid gas and methyl phosphine; both gases disappear completely, the salt condensing in well-defined four-sided plates. It is so volatile that it volatilises with ether-vapour. Its solution in concentrated hydrochloric acid gives, with platinum chloride, a double salt forming orange-red crystals. The hydriodide, $\text{PH}^2(\text{CH}^3).\text{HI}$, is obtained in thick crystals, by passing the gas into highly-concentrated hydriodic acid. By passing the gas into concentrated sulphuric acid, it is absorbed without blackening of the liquid, and set free again on addition of water. The sulphite is an amorphous white mass, obtained by mixing sulphurous acid and methyl phosphine over mercury. Carbonic acid and hydrogen sulphide do not act upon it, but it combines with sulphur, carbon bisulphide, and chlorocarbonic ether.

Dimethyl Phosphine, $\text{PH}(\text{CH}^3)_2$, is a colourless liquid, lighter than water, and insoluble therein. It boils at 25° , or at the same temperature as its isomeride, ethyl phosphine, $\text{PH}^2\text{C}^2\text{H}^5$. It takes fire at once in contact with air, burning with a bright phosphorus flame. Its salts are all very soluble; the hydrochloride forms with platinum chloride a well-crystallised double salt. It also combines with sulphur and carbon bisulphide.

Isopropyl Phosphines (Hofmann, *Deut. Chem. Ges. Ber.* vi. 292). These bases are obtained by heating the corresponding iodides with phosphonium iodide and zinc

oxide to 100° for 5 or 6 hours. The primary and secondary bases are easily separated from one another, like the corresponding methyl- and ethyl-compounds, by treating the hydriodides with water, which decomposes the primary compounds, whereas the secondary hydriodides are decomposed only by alkalis.

Isopropyl Phosphine, $\text{PH}^3(\text{C}^3\text{H}^7)$, is a light, limpid, very refractive liquid, boiling at 41°, and having a very penetrating odour. It unites with sulphur and with carbon bisulphide, forming uncrystallisable compounds. It readily absorbs oxygen and takes fire on a hot summer day.

Diisopropyl Phosphine, $\text{PH}^2(\text{C}^3\text{H}^7)_2$, boils at 118°. It absorbs oxygen more quickly than the primary base, a drop placed on filter-paper taking fire and blackening the paper slightly without inflaming it.

Triisopropyl Phosphine, $\text{P}(\text{C}^3\text{H}^7)_3$, the hydriodide of which is obtained by heating diisopropyl-phosphine with isopropyl iodide to 120°, is a liquid forming a red crystallisable compound with carbon bisulphide. The hydriodide, $\text{P}(\text{C}^3\text{H}^7)_3\text{HI}$, forms large crystals readily soluble in water and in alcohol, but insoluble in ether.

Tetrisopropyl-phosphonium iodide, $\text{P}(\text{C}^3\text{H}^7)_4\text{I}$, formed by combining the tertiary base with isopropyl iodide, crystallises from water in cubes or octohedrons.

Methyl-isopropyl Phosphine, $\text{PH}(\text{CH}^3)(\text{C}^3\text{H}^7)$, is obtained as a hydriodide by heating the primary propyl base with methyl iodide to 100°. The free base boils at 78°-80°.

Isobutyl Phosphines (Hofmann, *loc. cit.*) These bases are prepared similarly to the isopropyl-phosphines. **Isobutyl phosphine**, $\text{PH}^2(\text{C}^4\text{H}^9)$, boils at 62°; **diisobutyl phosphine**, $\text{PH}(\text{C}^4\text{H}^9)_2$, at 153°. Both are oily liquids having the general properties of the phosphines. The secondary base combines with isobutyl iodide at 100°, forming a beautiful crystalline mass of **triisobutyl-phosphine iodide**, $\text{P}(\text{C}^4\text{H}^9)_3\text{I}$. Free triisobutyl-phosphine boils at 216°; it unites with isobutyl iodide, but the tetrisobutyl-phosphonium iodide has not been obtained in the pure state.

As the tertiary phosphorus-bases and phosphonium-compounds are also produced by heating the alcohols with phosphonium iodide, an attempt was made to prepare the corresponding isobutyl-compounds by heating isobutyl alcohol with phosphonium iodide; but no phosphines were formed, the alcohol being decomposed with formation of hydrocarbons.

Isopropyl-isobutyl Phosphine, $\text{PH}^2(\text{C}^3\text{H}^7)(\text{C}^4\text{H}^9)$, is formed, as hydriodide, by heating isopropyl phosphine and isobutyl iodide to 130°; it boils at 139°-140°. Heated with ethyl iodide to 100° it yields **ethyl-isopropyl-isobutyl phosphine**, a very oxidisable liquid, boiling at about 190°.

Methyl-triisobutyl-phosphonium iodide, $\text{P}(\text{CH}^3)(\text{C}^4\text{H}^9)_3\text{I}$. Methyl iodide acts on triisobutyl phosphine with explosive violence. The crystalline product is purified by dissolving it in water, adding an alkali, distilling off the volatile phosphines, then treating the solution with carbonic acid, evaporating to dryness, and exhausting with alcohol. The crystalline residue is readily soluble in water, from which it separates in fine crystals. A very similar body is **methyl-ethyl-isopropyl-isobutyl-phosphonium iodide**, which is obtained by combining methyl iodide with ethyl-isopropyl-isobutyl phosphine.

Isoamyl Phosphines, $\text{PH}^2(\text{C}^5\text{H}^{11})$. The phosphines of isoamyl (ordinary amyl) are but slowly formed at 100°, but readily at 140°-150°. The primary base boils at 106°-107°, and absorbs oxygen with evolution of heat. **Diisoamyl phosphine**, $\text{PH}(\text{C}^5\text{H}^{11})_2$, boils at 210°-215°. A drop placed on litmus paper is oxidised, with formation of dense white phosphorescent fumes, without taking fire. **Triisoamyl phosphine**, $\text{P}(\text{C}^5\text{H}^{11})_3$, boils at about 300°, but has not been obtained pure. In one experiment some tetramyl-phosphonium iodide was formed, which, on addition of an alkali, separated as a viscid liquid, but became crystalline on standing for some months.

Triisoamyl-phosphine oxide, $\text{P}(\text{C}^5\text{H}^{11})_3\text{O}$, is always formed in small quantity in the preparation of triisoamyl phosphine. It boils above 360°, and solidifies, after the phosphine has distilled over, in the neck of the retort, to a crystalline mass which melts at 60°-65°. Water precipitates it from an alcoholic solution as a crystalline powder (Hofmann, *ibid.* vi. 301).

When amyl alcohol and phosphonium iodide are heated to 150°, they yield amyl iodide and hydrogen phosphide, whilst at 170°-180° gaseous hydrocarbons are formed.

Benzyl Phosphines (Hofmann, *ibid.* v. 100). These compounds are easily formed by heating crude benzyl chloride with phosphonium iodide and zinc oxide. On distilling the product with steam, a heavy oil passes over, being a mixture of benzyl phosphine and regenerated toluene, which are separated by fractional distillation.

Benzyl Phosphine, $\text{PH}^2(\text{C}^6\text{H}^5)$, boils at 180°. In contact with the air it quickly takes up oxygen, thick white fumes being formed and the temperature rising 100° or

more. The *hydriodide* is crystalline and is decomposed by water. The *hydrobromide* and *hydrochloride* do not crystallise; the latter forms a yellow precipitate with platinum chloride.

Dibenzyl Phosphine, $\text{PH}(\text{C}^6\text{H}_5)_2$, is formed, together with the primary base, and remains behind on distillation. It crystallises from alcohol in large, scentless, and tasteless needles, grouped in stars or fascicles; they melt at 206° and volatilise, with partial decomposition, at a higher temperature. It is insoluble in all acids, permanent in the air, even at rather high temperatures.

The aromatic phosphines, analogous to aniline and toluidine, have not yet been obtained.

Formation of Phosphines by the aid of Reduction-Processes.

The *phosphines of polygenic radicles* cannot be obtained by the same reaction as that by which the phosphines of monatomic radicles are prepared, on account of the reducing action of hydriodic acid. Zinc oxide and phosphonium iodide act on ethylene dibromide at 160° , yielding however nothing but ethyl phosphine. Chloroform is acted on at 100° , but the product is only methyl phosphine. Benzylene chloride, $\text{C}^6\text{H}_4\text{CHCl}_2$, and the chloride, $\text{C}^6\text{H}_5\text{CCl}_2$, yield only the phosphines of benzyl, which therefore can be readily obtained pure by employing the crude product of the action of chlorine on boiling toluene. For the same reasons crude isopropyl iodide containing allyl iodide yield pure isopropyl phosphine (Hofmann, *ibid.* v. 301).

PHOSPHINIC ACIDS (Hofmann, *ibid.* v. 104; vi. 303). These acids are formed from the primary and secondary phosphines by fixation of 3 and 2 atoms of oxygen respectively, and may be regarded as orthophosphoric acid, $\text{PO}(\text{OH})_3$, in which one or more of the groups OH is replaced by an alcohol-radicle. They are prepared by treating the corresponding phosphines with nitric acid. The complete oxidation of the phosphorus to phosphoric acid takes place only when the phosphines are heated with the strongest nitric acid, and at very high temperatures.

Methyl-phosphinic acid, $\text{PH}^2(\text{CH}_3)_2\text{O}^2$, or $\text{PO}(\text{HO})(\text{CH}_3)$, is formed by passing gaseous methyl phosphine, evolved on treating with water the crude product of the action of methyl iodide on phosphonium iodide and zinc oxide, into fuming nitric acid. To purify it from a small quantity of phosphoric acid formed at the same time, from phosphoretted hydrogen present in the gas, the nitric acid solution is evaporated on a water-bath, and the residue is dissolved in water and treated with lead oxide, which gives a salt insoluble in water but soluble in acetic acid. The acetic solution filtered from the insoluble phosphate, and freed from lead by hydrogen sulphide, leaves on evaporation an oily liquid which solidifies on cooling to a white mass resembling spermaceti. This substance is methyl-phosphinic acid; it is easily soluble in water, reddens litmus paper, and has an agreeable acid taste. It also dissolves in alcohol, and to a smaller extent in ether. It is remarkably stable, not being acted upon by fuming nitric acid, or even by evaporation with aqua regia. It melts at 105° , and volatilises in great part without decomposition. It is isomeric with methyl-phosphorous acid, but differs greatly in its properties from that compound, which is uncrystallisable, and is resolved at a gentle heat into phosphorous acid and methyl alcohol.

Methyl-phosphinic acid forms two classes of salts, $\text{PHR}(\text{CH}_3)_2\text{O}^2$ and $\text{PR}^2(\text{CH}_3)_2\text{O}^2$, the former having an acid, the latter an alkaline reaction. The alkali salts are soluble and only slightly crystalline; the ammonia salt loses ammonia on evaporation, and leaves the acid. Many of the heavy metallic salts are insoluble or dissolve with difficulty.

The primary or *monargentate salt*, $\text{PHAg}(\text{CH}_3)_2\text{O}^2$, crystallises in white needles, and is easily resolved by water, or even by alcohol, into the free acid and the secondary or *diargentate salt*, $\text{PAg}^2(\text{CH}_3)_2\text{O}^2$, which is a white insoluble powder. The *primary lead salt* is also decomposed by water; the *secondary lead salt*, $\text{P}(\text{CH}_3)_2\text{PbO}^2$, is easily obtained pure as a white precipitate, almost insoluble in water, but soluble in acetic acid. The *primary barium salt*, $\text{P}^2(\text{CH}_3)_2\text{H}^2\text{BaO}^2$, is obtained in white microscopic needles by adding alcohol to its concentrated aqueous solution, or as a gummy mass.

Dimethyl-phosphinic acid, $\text{PH}(\text{CH}_3)_2\text{O}^2 = \text{PO}(\text{OH})(\text{CH}_3)$, is obtained by mixing a solution of dimethyl phosphine in hydrochloric acid with fuming nitric acid, and, after the reaction is over, evaporating the liquid, saturating with silver oxide, and treating the solution of the silver salt with hydrogen sulphide. On evaporating the resulting acid solution, dimethyl-phosphinic acid is obtained as a white crystalline mass, becoming slightly brown in contact with the air. It is very soluble in water, alcohol, and ether, the solutions having an acid reaction. The crystals melt at 70° , volatilise without decomposition at a higher temperature, and the distilled product exhibits an unchanged melting point.

Dimethyl-phosphinic acid forms only one series of salts, having the composition

$P(CH^3)_3RO^3$. The *silver salt*, $P(CH^3)_3AgO^3$, forms white needles extraordinarily soluble in water, but very slightly soluble in absolute alcohol and ether. The barium and lead salts are neutral, very soluble, uncrystallisable compounds.

Methyl-phosphinic chloride, $P(CH^3)_2OCl^2$, is obtained by the action of phosphorus pentachloride on methyl-phosphinic acid. It is a crystalline solid, melting at 32° and boiling at 183° . Water, alcohol, ammonia, and aniline, act violently on it as on other acid chlorides.

Dimethyl-phosphinic chloride, $P(CH^3)_2OCl$, melts at 66° and boils at 204° . Water and alcohol decompose it, but with less violence than the preceding compound.

Ethyl-phosphinic acid, $P(C^2H^5)_2H^3O^3$, is prepared like the corresponding methyl-compound, which it resembles in appearance and many of its properties. It melts at 44° . Its *silver salt* is an amorphous yellowish powder, insoluble in water and in alcohol.

Diethyl-phosphinic acid has not been obtained in the crystalline state, but only as a liquid which does not solidify at -25° . The *silver salt*, $P(C^2H^5)_2AgO^3$, is crystalline.

Isopropyl-phosphinic acid, $P(C^3H^7)_2HO^3$, prepared like the corresponding ethyl- and methyl-compounds, is a white mass resembling paraffin, and melting between 60° and 70° ; it dissolves in water, and more freely in alcohol.

Isobutyl-phosphinic acid is a very similar body, melting at 100° .

Amyl-phosphinic acid, $P(C^5H^{11})_2HO^3$, is prepared by adding amyl phosphino to a mixture of equal volumes of fuming nitric acid and nitric acid of sp. gr. 1.2; the fuming acid alone acts too violently and sets fire to the base. The acid crystallises from hot water in small pearly rhombic plates melting at 160° . The silver salts of this acid and of the two acids last described are white amorphous precipitates.

The secondary phosphines of isopropyl, isobutyl, and amyl, yield, by oxidation with nitric acid, the corresponding phosphinic acids, which, however, have not yet been obtained in a state fit for analysis; neither have any of their salts been prepared in the pure state. The free acids are oily liquids insoluble in water.

PHOSPHOCHROMITE. This name is given by R. Hermann (*J. pr. Chem.* [2], i. 449) to a mineral from Beresovsk in Siberia, hitherto regarded as rauquelinite, to which he assigns the formula $3(2CuO.P^2O^3) + 5(3PbO.CrO^3) + 3H^2O$. Implanted in listwaenite, and accompanied by lead chromate and pyromorphite, it forms a nodular aggregate exhibiting small crystals on its surface (thin laminae with rounded end-faces). Blackish-green; yields a siskin-green powder. Hardness = 3; sp. gr. = 5.80. Analysis gave:

PbO	CaO	FeO	CrO ³	P ² O ³	H ² O
68.33	7.36	2.80	10.13	9.94	1.16 = 99.72.

PHOSPHOPLATINUM COMPOUNDS. See PLATINUM (p. 987).

PHOSPHORITE. See PHOSPHATES (pp. 969, 974).

PHOSPHORUS. *Quantivalence.*—Wicholhaus (*Ann. Ch. Pharm., Suppl.* vi. 257); *Jahresb. f. Chem.* 1868, 148) regards phosphorus as a trivalent element, founding his opinion mainly on the action of chlorine on ethyl-phosphorous chloride and that of phosphorus bromochloride on benzoic acid. Geuther u. Michaelis, however (*Jenaische Zeitschrift*, vi. 242; *Jahresb.* 1870, 276), have shown that these reactions may be better explained on the generally received view that the maximum quantivalence of phosphorus is 5.

Allotropic modifications: Black Phosphorus.—This modification, originally obtained by Blondlot, by the sudden cooling of melted phosphorus (iv. 503), may also be produced by distilling ordinary phosphorus with a trace of mercury, or by heating it to 100° for several hours with mercury under water. The product obtained by either of these two methods is not homogeneous, but owes its colour to a large number of black specks more or less irregularly distributed; on fusion, these specks disappear, and the phosphorus turns white, resuming its black colour, however, on cooling. On treating the phosphorus with carbon sulphide, this black matter remains undissolved in extremely small quantity. The quantity of it does not appear to be increased either by prolonged contact of the phosphorus with the mercury, or by the quantity of the latter present. By repeated distillation, whereupon the black substance passes over first, a product may be obtained free from mercury (*Compt. rend.* lxx. 856).

Conversion of Ordinary into Red Phosphorus in Sunshine.—Phosphorus dissolved in carbon sulphide behaves like sulphur when exposed to sunshine. Where the sun's rays fall upon it, a yellow spot of amorphous phosphorus is formed, quickly changing to brown-red; the action is, however, less energetic than in the case of sulphur, and requires a longer time. The transmitted light contains all the luminous rays, the light being merely fainter near the line H. The least refrangible of the chemical

rays may still be detected by their effect on phosphorescent bodies; but beyond N all the chemical rays have disappeared (A. Lallemand, *Compt. rend.* lxx. 182).

Reciprocal Transformation of Ordinary and Red Phosphorus.—The conditions of these transformations have been investigated by G. Lemoine (*Compt. rend.* lxxiii. 797, 837, and 990; *Chem. Soc. J.* [2], ix. 1167). The experiments were made at the boiling point of sulphur (440°) in Deville's apparatus (v. 373). The flasks (of 60 to 600 c.c. capacity) were exhausted of air after the introduction of the phosphorus, then closed and heated in every part to 440°; then, after a certain time, they were very quickly cooled with warm water, to avoid the occurrence of intermediate temperatures; the two modifications of phosphorus were separated by carbon sulphide and their quantities determined. From a large number of experiments Lemoine concludes that the conversion of ordinary into red and of red into ordinary phosphorus is essentially dependent on vapour tension. The conversion is never complete, but its rapidity depends in a great measure on the quantity of phosphorus originally present, and diminishes the more nearly a certain limit of transformation is approached. In fact, whichever of the two allotropic modifications is operated on, the transformation always tends towards the same limit, viz., the production of about 3.6 grams of ordinary phosphorus per litre of space.

According to Troost & Hautefeuille (*Compt. rend.* lxxvi. 76, 219; *Chem. Soc. J.* [2], xi. 599), the transformation of ordinary into red phosphorus, like that of cyanic acid into cyanide (1st Suppl. 518), obeys different laws accordingly as the phosphorus is in the liquid or the vaporous state. The liquid element, at 280° for instance, is analogous to liquid cyanic acid, being wholly transformed into red phosphorus. The vapour given off at 260° is stable; but that formed at higher temperatures is slowly and partially converted into red phosphorus, the production of which ceases when the tension has attained a given minimum; the rapidity with which this change is effected is greater the higher the temperature.

Luminosity of Phosphorus.—W. Müller (*Pogg. Ann.* cxli. 95) finds, in accordance with earlier observations (iv. 503), that phosphorus is not oxidised, and does not shine in pure oxygen under ordinary atmospheric pressure, but that on rarifying the oxygen, either by means of the air-pump, or by admixture of foreign gases, the phosphorus shines at ordinary temperatures, and at a lower temperature the greater the dilution of the gas. Oxidation begins at 10°–11°, when the oxygen is expanded by about $\frac{1}{2}$ of its original volume, or at 17.5° when 1 vol. nitrogen is added to every 1.5 vol. oxygen, or at 16° when an equal volume of hydrogen is added. The volatilisation of the phosphorus is not interrupted by the presence of substances which destroy the luminosity. Phosphorus is slightly soluble in water, and when bubbles of hydrogen containing air are passed through such phosphoretted water (filtered), they shine with a bright light.

Reaction with Ammonia.—According to Blondlot (*Compt. rend.* lvi. 1250), phosphorus left for a long time in contact with excess of aqueous ammonia in closed vessels is converted into a black friable substance which, on exposure to the air, turns yellow and gives off a small quantity of ammonia. According to Commaille, on the other hand (*Compt. rend.* lxxiii. 263; *Moniteur Scientifique* [3], i. 701), the product thus obtained is not black but green, and always has the composition P^2H . When boiled with water, it does not give off any gas, but only a whitish fume, and the water which distils over is alkaline, while that which remains behind has a faint acid reaction. On boiling the compound with sulphuric acid, the phosphorus dissolves, with separation of sulphur and formation of phosphorus trisulphide. Ordinary nitric acid acts strongly on the compound at ordinary temperatures, whereby it is distinguished from ordinary phosphorus and nitrogen phosphide. It differs also from the compound P^2H in not being set on fire by nitric acid. From a solution of cupric sulphate it throws down phosphide of copper, but not the metal, as is the case with phosphorus and P^2H . When triturated with potassium chlorate, it explodes violently. It is decomposed by potash, especially when heated, a character which distinguishes it from the compound described by Flückiger (iv. 505).

Phosphorus is not acted on by gaseous ammonia, and very little by a solution of ammonium carbonate; but alcoholic ammonia left for 2½ months in contact with phosphorus produced non-spontaneously inflammable phosphoretted hydrogen gas, the green powder above described, and small crystals, probably consisting of ammonium phosphite or hypophosphite. The alcohol evaporated on the water-bath left a syrupy mass which deposited crystals of unknown composition (Commaille).

Action of Phosphorus on Metallic Solutions.—When an ammoniacal solution of copper oxide, nickel oxide, silver oxide, or cadmium oxide is heated with phosphorus and a little benzene in a vessel connected with a reversed condenser, dark precipitates are formed, which may be washed with water, alcohol and carbon sulphide, and dried in vacuum. The copper precipitate consists chiefly of metallic copper and copper oxide.

Nickel gives a black precipitate consisting of a mixture of nickel phosphide and a salt of one of the acids of phosphorus. From the silver solution metallic silver is reduced (Oppenheim, *Deut. Chem. Ges. Ber.* v. 979).

Reaction with Turpentine Oil.—When $\frac{1}{2}$ oz. of phosphorus is gradually added to 2 pounds of ordinary turpentine-oil (containing oxygen) heated to 40° , the flask being removed from the sand-bath as soon as the phosphorus melts, and agitated, the liquid on cooling deposits the excess of phosphorus, which quickly turns red, and a white crystalline, spermaceti-like mass consisting of turpentine-phosphorous acid, said to have the composition $C^{10}H^{16}PO^2$. This compound has an acid reaction, and is converted, on exposure to the air, into a resinous substance, smelling like pine-resin, in which phosphoric acid can be directly detected. It melts at 50° , with decomposition, to a yellow resinous mass, and decomposes in a stream of hydrogen at 40° , with evolution of spontaneously inflammable phosphoretted hydrogen. With earths and metallic oxides it forms insoluble salts. The acid is not poisonous; doses of 0.03 to 0.3 gram may be given to dogs and rabbits without any other effect than a lowering of the bodily temperature. Its formation appears to be the cause of the action of turpentine-oil as an antidote to poisoning by phosphorus (Köhler a. Schimpf, *Dingl. pol. J.* cxcix. 510).

Haloid Compounds of Phosphorus.

Chlorides. 1. **Trichloride or Phosphorous Chloride, PCl_3 .**—**Reactions.**—With Bromine. According to Michaelis (*Deut. Chem. Ges. Ber.* v. 9), phosphorous chloride unites directly with bromine, forming the compound PCl_2Br_2 ; according to Pinnault (*Compt. rend.* lxxiv. 868), the product has the composition PCl_2Br^2 (see CHLOROBROMIDES, p. 961).

2. **With Water.**—The decomposition of phosphorous chloride by water is sometimes attended with separation of phosphorus. From experiments by Kraut (*Ann. Ch. Pharm.* clviii. 333), it appears that when the chloride is added by drops to ice-cold water, with continual stirring, only a trace of phosphorus is obtained; but if the chloride is dropped into boiling water, each addition is attended by a luminous appearance and considerable separation of amorphous phosphorus. The luminous appearance can be avoided by using moderately warm water, when also phosphorus is obtained. When trichloride of phosphorus is distilled with a little water, or, what is the same thing, with phosphorous acid, phosphorus separates in reddish-yellow drops, and the residue contains orthophosphoric acid. The reaction would seem to be as follows:—

Tribromide of phosphorus behaves with phosphorous acid in a similar way to the trichloride, but the decomposition takes place at a somewhat higher temperature. Geuther (*Jenaische Zeitschr.* vii. 122) finds that, with water at 80° , only a very slight deposition of phosphorus takes place; with water which had been boiling for a moment before the experiment, he noticed an appearance near the mouth of the test-tube which contained the water, much resembling phosphorescence, but no phosphorus was separated. By varying the conditions of the experiment, he has been led to conclude that it is only in presence of an excess of air, that the phosphorescent phenomena are exhibited by the phosphorous chloride when dropped into water. He supposes that part of the phosphorous chloride is rendered gaseous; this is decomposed, giving part of the phosphorous chloride is rendered gaseous; this is decomposed, giving hydrochloric acid and phosphorous acid, which, by the excess of oxygen present, is oxidised to phosphoric acid: a small part of the phosphorous acid formed may be reduced to phosphoretted hydrogen, and this again decomposed, giving water and free phosphorus, and hence the small quantity of separated phosphorus.

Distilled with a solution of phosphoric acid, phosphorous chloride gives hydrochloric acid, free phosphorus, and phosphorus oxychloride.

3. **With Anhydrides and Chlorides** (Michaelis, *ibid.* vi. 239; vii. 110). Phosphorous chloride does not exhibit very great affinity for oxygen at ordinary temperatures, but the affinity increases very rapidly with the temperature, so that at high temperatures phosphorous chloride is capable of decomposing very stable compounds; it belongs therefore to the class of reducing agents. When the compound on which it acts contains any element which has a powerful affinity for chlorine, a large quantity of phosphoric acid is produced, with but little oxychloride of phosphorus. Thus most metallic oxides form chlorides and phosphates, with but little phosphorus oxychloride. The only oxide directly reduced to metal by phosphorous chloride is lead oxide. Antimony liberates the phosphorus and is itself converted into trichloride.

Liquid **phosphorous anhydride** mixes with phosphorous chloride at ordinary temperatures without evolution of heat, and the two bodies may be heated together in a sealed tube to 140° , without producing any sensible reaction; but when passed together in

the state of vapour through a red-hot tube, they yield oxychloride and sulphochloride of phosphorus, thus:

With *sulphuric anhydride*, phosphorous chloride reacts energetically, even when both substances are cooled, the products being sulphurous anhydride and phosphorus oxychloride:

With *sulphuric chlorhydrate* (sulphuryl-hydroxyl chloride) reaction takes place in the cold, yielding disulphuric (pyrosulphuric) chloride:

With *disulphuric chloride* the reaction is:

With *sulphurous chloride* (thionyl chloride) reaction takes place slowly but completely at 160° in sealed tubes, yielding the preceding products, together with phosphorus pentachloride:

With *sulphur chloride*, S^2Cl^2 , the products are pentachloride and sulphochloride of phosphorus, the action being more energetic than in the last case:

This is a convenient way of preparing the sulphochloride.

With *arsenious oxide* the reaction,

takes place directly, without previous formation of phosphorus oxychloride.

With *arsenic oxide* no reaction appears to take place even at 200° .

With *chromic oxychloride* a very energetic action takes place, accompanied by a hissing noise and emission of light: hence the phosphorous chloride must be well cooled and the chromic oxychloride added by drops. The reaction is:

The phosphorus pentachloride, however, acts partially on the anhydride, producing an additional quantity of oxychloride:

When phosphorous chloride was heated to 166° for two days with *potassium dichromate*, the latter was partly converted into chlorochromate, apparently according to the equation:

With *antimonious oxide* phosphorous chloride yields amorphous phosphorus and antimonious chloride. Now, as arsenious oxide and phosphorous chloride yield phosphoric anhydride, arsenious chloride, and free arsenic (*supra*), it may be supposed that in the present case metallic antimony was first set free and then liberated phosphorus from the chloride; and this view is confirmed by direct experiment. Arsenic and bismuth heated with phosphorous chloride separate only traces of phosphorus. Hence it follows that antimony, at least at high temperatures, has a greater affinity to chlorine than phosphorus, arsenic, or bismuth.

Antimonic oxide and *bismuth trioxide* are decomposed by phosphorous chloride according to the equations:

Lead oxide and phosphorous chloride do not act on one another at 160° ; but when lead oxide is moistened with phosphorous chloride and heated directly over a lamp, a violent action takes place attended with ignition, and a large quantity of lead is reduced:

This experiment is very well adapted for exhibiting the reducing action of phosphorous chloride.

Lead dioxide acts on heated phosphorous chloride, with ignition, according to the equation:

Stannic oxide and *cupric oxide* act on phosphorous chloride at 160°, according to the equations:

Cupric oxide, moistened with phosphorous chloride and heated rather strongly over a lamp, is decomposed, according to the above equation, with ignition and appearance of flame.

Precipitated *mercuric oxide* acts on phosphorous chloride even at ordinary temperatures, in exactly the same manner as cupric oxide; the crystallised oxide acts only when heated in a sealed tube to 160°.

Molybdic trioxide, in contact with phosphorous chloride, even at ordinary temperatures, becomes heated and acquires a blue colour; on heating the substances together in a sealed tube to 160°, the contents turn brown. The action probably takes place according to the equations:

Tungstic trioxide, heated with phosphorous chloride even to 200°, merely turns green on the surface without undergoing any further alteration.

Manganese dioxide and *ferric oxide* appear also not to be acted on by phosphorous chloride.

Chlorobromide, PCl^3Br^2 (Michaelis, *Deut. Chem. Ges. Ber.* v. 9). This compound is formed by direct combination of bromine with phosphorous chloride. According to Wichelhaus, the two bodies unite, with evolution of heat, to form a compound which crystallises in a freezing mixture, but separates at ordinary temperatures into two liquid layers; and he considers that the compound is broken up on liquefaction just as PCl^3 is resolved into $\text{PCl}^3 + \text{Cl}^2$ when vaporised. Michaelis, on the other hand, finds that it possesses considerable stability, even at ordinary temperatures. The combination takes place but slowly; and when phosphorous chloride and bromine are first mixed, a liquid is obtained consisting of two layers—solutions respectively of phosphorous chloride in bromine, and of bromine in phosphorous chloride. In a freezing mixture at -20° this liquid solidifies, but separates again into two layers on fusion. If, however, the mixture be allowed to remain undisturbed in a sealed tube at winter temperature for about a week, a crystalline mass is obtained which does not form two layers again at ordinary temperatures, but a homogeneous liquid.

Phosphorus chlorobromide is a yellowish red mass resembling phosphorus pentabromide. At 35° it is resolved into PCl^3 and Br^2 . Water has the same action upon it as upon a mixture of phosphorous chloride and bromine:

The chlorobromide is decomposed by *sulphur dioxide*, yielding phosphorus oxychloride and sulphur tetrabromide:

the latter, however, being resolved by distillation into SBr and Br^2 (Michaelis, *Jenaische Zeitschr.* vi. 296).

When a crystal of the compound PCl^3Br^2 , or even a portion of the phosphorous chloride which covers these crystals at the time of their formation, is introduced into a mixture of phosphorous chloride and bromine, the lower layer immediately solidifies to a mass consisting of the compound PCl^3Br^4 . Michaelis explains the formation of this compound on the supposition that the lower layer of liquid formed on mixing phosphorous chloride with bromine is a supersaturated solution of PCl^3Br^2 in bromine. At the moment when crystallisation is set up by the introduction of solid PCl^3Br^2 , the latter unites with the excess of bromine and crystallises out with it, just as a salt separates from aqueous solution in combination with water of crystallisation. The compound, PCl^3Br^4 , forms large fine crystals having a dark red colour with a blue reflex. When heated it melts to a dark red liquid, which gradually separates into two layers, but on solidification the original crystals reappear. They are decomposed by a large quantity of water into phosphoric, hydrochloric, and hydrobromic acids and free bromine; by a small quantity of water, into chloride and bromide of phosphoryl, hydrochloric and hydrobromic acids, and free bromine. Dry sulphur dioxide decomposes them in the manner represented by the equation:

Bromochlorides of phosphorus, containing still larger quantities of bromine, have been obtained by Prinsault (*Compt. rend.* lxxiv. 368). When bromine is added to

phosphorous chloride till the two layers first formed have disappeared, and the whole is heated in the water-bath to 65° as long as bromine continues to escape, there remains a red-brown oily liquid which solidifies, at 4° or 5° above 0° , to brown metallic lustrous needles having the composition $\text{PCl}^2\text{Br}^2 = \text{PBr}^2.3\text{ClBr}$. This compound may be distilled without decomposition below 90° , and its vapour is colourless. By rapid distillation above 90° it is decomposed, yielding the compound PCl^2Br , which collects in the receiver in fine prismatic crystals. This last compound is also formed when phosphorous chloride is dropped into bromine till two layers of liquid are formed. Fine crystals then form after a while, sometimes 2 or 3 mm. long. These crystals dissolve in phosphorous chloride at ordinary temperatures, and, on heating the solution to the boiling point of the chloride, yellow crystals are deposited consisting of the compound PCl^2Br or $\text{PCl}^2.\text{ClBr}$, which is also produced by the action of bromine chloride on phosphorous chloride. By means of this compound Prinvaux has obtained the tetrabrominated compound, PCl^2Br^4 , already described, the formation of which may perhaps be represented by the equations:

Michaelis (*Deut. Chem. Ges. Ber.* v. 414) has repeated Prinvaux's experiments with somewhat different results. By adding bromine in excess to phosphorous chloride, so that about 4 mols. bromine should be present for every 1 mol. PCl^2 , he obtained, with somewhat considerable rise of temperature, a uniform oily liquid which, after a few minutes, began to deposit a large quantity of crystals, and solidified completely after about two hours. These crystals were brown needles with a beautiful green metallic reflex, but so unstable that they could not be completely separated from the mother-liquor. They had nearly the composition PCl^2Br^2 , and melted at about 25° , the liquefied mass solidifying again completely on cooling. At temperatures below 90° its vapour is not colourless, but has the colour of bromine-vapour.

Prinvaux regards the compounds above described as compounds of phosphorus pentabromide with bromine chloride, ClBr . On this view the action of sulphur dioxide upon them should give rise to phosphoryl tribromide, POBr^3 , and bromine chloride; this, however, is not the case, the actual products being phosphoryl trichloride, sulphur bromide, and free bromine. This makes it probable that the bodies in question are additive compounds of bromine with PCl^2Br^2 , namely $\text{PCl}^2\text{Br}^2.\text{Br}^2$, and $\text{PCl}^2\text{Br}^2.3\text{Br}^2$, analogous in constitution to $\text{PCl}^2.\text{ICl}$, $\text{PCl}^2.\text{FeCl}^2$, &c. (Michaelis).

Oxychlorides. *Phosphoryl Trichloride*, POCl^3 .—This compound, cooled down to -10° , remains liquid even when shaken, but when touched with a solid body, such as the end of a glass rod, it immediately solidifies to a crystalline mass. The long, colourless, leaf-like crystals melt at -1.5° . Below this temperature they are permanent, and will lie upon ice for some time without decomposing. A small crystal is sufficient to cause a considerable quantity of the liquid oxychloride, cooled to -2° , to solidify completely (Geuther a. Michaelis, *Deut. Chem. Ges. Ber.* iv. 769). According to Thorpe (*Chem. Soc. J.* [2] ix. 1162), the melting point of this compound is $+2.5^{\circ}$.

Phosphoryl trichloride unites very easily with boron trichloride, forming the compound $\text{PBOCl}^3 = \text{POCl}^3 + \text{BCl}^3$, which, however, is completely resolved by sublimation into its components (see Boron, p. 207).

Phosphoryl bromodichloride, POBrCl^2 , solidifies at 0° to large colourless crystals which liquefy at $+11^{\circ}$. The crystals of this compound appear to be isomorphous with those of the trichloride and tribromide of phosphoryl (Geuther a. Michaelis).

Pyrophosphoryl Chloride, $\text{P}^2\text{O}^2\text{Cl}^4$ (Geuther a. Michaelis, *Deut. Chem. Ges. Ber.* iv. 766).—This compound, the analogue of pyrophosphoric acid, $\text{P}^2\text{O}^2(\text{OH})^4$, is formed, together with phosphoryl chloride, by the action of nitrogen tetroxide on tetroxide on cooled phosphorous chloride. The best way of preparing it is to allow the vapours of the liquefied tetroxide (prepared from lead nitrate) to pass into phosphorous trichloride cooled by a freezing mixture (20 grams NO^2 to 100 grams PCl^3). The reaction commences immediately, with evolution of nitrogen, nitrogen dioxide, and vapours of nitrosyl monochloride (NOCl). The phosphorus trichloride becomes redened by the presence of the last-mentioned compound, and phosphorus pentoxide separates out. When the whole of the nitrogen tetroxide has been added, the freezing mixture is replaced by lukewarm water in order to distil off the nitrosyl chloride. The liquid remaining is then rectified. Much unattacked phosphorus trichloride first passes over, next a considerable amount of phosphoryl trichloride, after which the boiling point rises rapidly to 200° , between which temperature and 230° the new compound distils over. It is advisable to prepare a large quantity of material by repetitions of the above operation before commencing to rectify. 360 grams of phosphorus

trichloride yielded 232 grams of phosphoryl trichloride, and only 40 grams (11.4 p.c.) of the pyrophosphoryl chloride.

Pyrophosphoryl chloride is a colourless liquid, which boils between 210° and 215° , and decomposes slightly on distillation into phosphoryl trichloride and phosphorus pentoxide: $3\text{P}^2\text{O}^4\text{Cl}^4 = 4\text{POCl}^3 + \text{P}^2\text{O}^5$. It fumes in the air and carbonises corks. Its specific gravity is 1.58 at 7° . It does not solidify at -18° on contact with a solid body. It is immediately decomposed by water, producing hydrochloric and ordinary phosphoric acid.

The constitution of pyrophosphoryl chloride may be represented by the formula:

the two univalent groups POCl^2 being held together by an atom of bivalent oxygen. This view of its constitution is confirmed by its reactions with pentachloride and pentabromide of phosphorus, with the former of which it yields 3 mols. phosphoryl trichloride, and with the latter 2 mols. phosphoryl bromodichloride and 1 mol. phosphoryl bromide:

With *alcohol*, pyrophosphoryl chloride yields ethyl-phosphoric chloride, a portion of which is decomposed by the water simultaneously formed, into ethyl-phosphoric acid and hydrochloric acid:

As pyrophosphoryl chloride when decomposed by water yields, not pyrophosphoric but orthophosphoric acid, the former acid should perhaps be represented, not by the formula $\text{PO}(\text{OH})^3-\text{O}-\text{PO}(\text{OH})^3$, but by the unsymmetrical formula:

Attempts were made to obtain pyrophosphoryl chloride by the action of nitrous acid on phosphoryl chloride, according to the equation:

also by the very gradual action of phosphorus pentoxide on the pentachloride; but in both cases only with negative result.

The preparation of pyrophosphoryl bromide by the action of N^2O^4 or N^2O^3 on PBr^5 was likewise unsuccessful, the products consisting merely of ordinary phosphoryl bromide and phosphorus pentoxide.

Metaphosphoryl chloride, PO^2Cl (?), Gustavson (*Deut. Chem. Ges. Ber.* iv. 753), by heating equivalent quantities of phosphorus pentoxide and phosphoryl chloride in a sealed tube to 200° for six hours, obtained a very viscid, transparent mass, probably formed according to the equation $\text{P}^2\text{O}^5 + \text{POCl}^3 = 3\text{PO}^2\text{Cl}$.

Sulphobromides (Michaelis, *Ann. Ch. Pharm.* clxiv. 9; *Deut. Chem. Ges. Ber.* iv. 777, v. 4).

1. *Pyrophosphoric Sulphabromide*, $\text{P}^2\text{S}^2\text{Br}^4 = \text{PSBr}^2-\text{S}-\text{PSBr}^2$.—To prepare this compound, finely-powdered phosphorus trisulphide is moistened with carbon sulphide, and the required quantity of bromine (diluted with about an equal volume of carbon sulphide) is added by drops, with repeated shaking and continued cooling of the vessel. The carbon sulphide is then distilled off, the residual oily product is exhausted with ether, and the clear decanted solution is freed from ether by distillation in a stream of carbonic anhydride at as low a temperature as possible. The sulphobromide then remains as an oily liquid which is often turbid at first, but soon becomes quite clear on standing in a closed vessel.

Pyrophosphoric sulphobromide is a light yellow oily liquid, which in contact with the air fumes strongly and becomes turbid from separation of sulphur. Its odour is aromatic and pungent. Sp. gr. = 2.2621 at 17° . It is decomposed by distillation into pentasulphide and orthosulphobromide of phosphorus:

the ortho-compound being then further resolved into sulphur, and the compound

P^2Br^3S . The orthosulphobromide is also produced by heating the pyrosulphobromide with the pentabromide:

Pyrophosphoric sulphobromide is decomposed by water into sulphur, orthophosphoric sulphobromide, hydrogen sulphide, phosphorus, and a sulphuretted phosphoric acid, probably pyrosulphophosphoric acid, $P^2S^3(OH)^4$. The action of alkalis is like that of water, but more violent, and is not attended with separation of sulphur or of orthophosphoric sulphobromide.

With absolute alcohol, pyrophosphoric sulphobromide yields the following ethylated substitution-products.

Triethyl-pyrophosphoric Sulphobromide	$P^2S^3(OC^2H^5)^4Br$
Ethyl Pyrosulphophosphate	$P^2S^3(OC^2H^5)^4$
Diethoxyl-diethylsulphyl-pyrosulphophosphoric Ether	$P^2S^3(OC^2H^5)^2(SC^2H^5)^2$

2. *Metaphosphoric Sulphobromide*, PS^2Br .—This appears to be the substance insoluble in ether which is obtained in the preparation of the pyrosulphobromide. Michaelis attributes its production to the presence of phosphorus pentasulphide in the trisulphide used, and explains its formation by the following reaction:

With water this compound behaves like the pyrosulphobromide. With alcohol it forms a crystalline ether having the composition $P^2S^3O^2(C^2H^5)^4$ (Michaelis).

3. *Orthophosphoric Sulphobromide*, or *Sulphophosphoryl Bromide*, $PSBr^3$.—This compound was discovered by Baudrimont, who obtained it by the action of hydrogen sulphide on phosphorus pentabromide (iv. 605). It is also produced, as above stated, by heating the pyrosulphobromide either alone or with phosphorus pentabromide. But the easiest way of preparing it is to add 8 pts. of bromine by drops to a solution of 1 pt. phosphorus and 1 pt. sulphur in carbon sulphide, keeping the liquid constantly cool. When the action is ended, the liquid is quickly distilled over as large a flame as possible, and the first portion of the distillate, which usually contains carbon sulphide, is collected apart. Part of the sulphobromide collects in the crystalline form in the neck of the retort; the rest passes over and remains dissolved in the liquid contents of the receiver. This liquid is repeatedly treated with fresh quantities of water, till the yellow oil, which at first collects at the bottom, has solidified to a yellow crystalline mass. The substance thus obtained is a hydrate of orthophosphoric sulphobromide, $PSBr^3.H^2O$. It has an aromatic tear-exciting odour, a specific gravity of 2.7937 at 18°, melts at 35°, and is resolved at the same time into water and the pure sulphobromide. It does not fume in the air, but gradually decomposes, with evolution of hydrobromic acid.

The anhydrous orthosulphobromide is obtained by treating the solution of the hydrate in carbon sulphide with calcium chloride, and remains, on evaporating the carbon sulphide, as a yellow liquid which for the most part does not solidify till touched with a solid body; it then forms a radio-crystalline mass. It melts at 38°, and exhibits in a high degree the phenomenon of superfusion. It dissolves easily in ether, carbon sulphide, phosphorous chloride, and phosphorous bromide, and crystallises from the last two solvents in yellow octohedrons belonging to the regular system.

Orthophosphoric sulphobromide is slowly decomposed by water in the cold, more quickly when heated, but a large portion passes over undecomposed with the aqueous vapour. The products of the decomposition are hydrobromic acid, large quantities of phosphorous acid and sulphur, and only small quantities of phosphoric acid and hydrogen sulphide, whereas the sulphochloride of phosphorus is resolved by water, as is well known, into hydrochloric acid, phosphoric acid, and hydrogen sulphide.

The formation of phosphorous acid and sulphur in the decomposition of the sulphobromide is explained by Michaelis as follows:—Sodium sulphophosphate, $PS(NaO)^2$, decomposed by free acids, yields hydrogen sulphide and phosphoric acid (Wüster). According to Michaelis, phosphorous acid and free sulphur are formed at the same time. Now, when $PSCl^3$ and $PSBr^3$ come in contact with water, either the chlorine (or bromine) or the sulphur may be removed by substitution. The former is the case with the sulphobromide, the products of its decomposition being HBr and $PS(OH)^3$, which latter is then resolved, partly by the further action of water, into $P(OH)^3$, & $PO(OH)^2$, and SH^2 ; whereas the sulphochloride exhibits the second form of decomposition, according to the equation:

the oxychloride then reacting with a further portion of water to form hydrochloric and phosphoric acids:

With *alcohol*, the sulphobromide forms ethyl monosulphophosphate, $\text{PS}(\text{OC}^2\text{H}^5)^2$.

Orthophosphoric sulphobromide does not volatilise wholly without decomposition, but is resolved by slow distillation into sulphur and the compound P^2SBr^4 or $\text{PSBr}^3 \cdot \text{PBr}^3$:

The compound, P^2SBr^4 , already mentioned as occurring amongst the products of the decomposition of the pyrosulphobromide by heat, is a yellow liquid which, when immersed in a mixture of ice and salt, solidifies to a white mass melting at -5° . By repeated distillation it is entirely resolved into sulphur and PBr^3 ; and by repeated washing with water it is converted into the hydrate of orthophosphoric sulphobromide, $\text{PSBr}^3 \cdot \text{H}^2\text{O}$.

Sulphochloride. *Sulphophosphoryl chloride*, PSCl^2 .—This compound is easily prepared by heating phosphorus pentasulphide with the pentachloride at 160° in a sealed tube, in the proportions required by the equation:

It is a liquid boiling at 126° under a barometric pressure of 770 mm. Its vapour is extremely pungent, but when mixed with air it has a pleasant aromatic odour (T. E. Thorpe, *Chem. News*, xxiv. 136).

Sulphochlorobromide, $\text{PS.Cl}^2\text{Br}$ (Michaelis, *Dent. Chem. Ges. Ber.* v. 146). To obtain this compound, ethylsulphophosphorous chloride, $\text{PCl}^2(\text{SC}^2\text{H}^5)$, (a colourless liquid boiling at 172° - 175°), is prepared by the action of phosphorous chloride on mercaptan, and bromine is added to it by drops in a vessel which is kept cool. The following reaction then takes place:

The resulting liquid is fractionally distilled; the portion boiling between 160° and 180° is agitated with water till no further action is perceptible; and the remaining liquid is separated from the water, dehydrated with calcium chloride, and freed by gentle heating from absorbed hydrochloric and hydrobromic acids.

Phosphorus sulphochlorobromide is a faintly yellow liquid having an aromatic pungent odour like that of the sulphochloride. It begins to boil at 150° , but the boiling point soon rises, the liquid undergoing partial decomposition, with separation of sulphur. It offers considerable resistance to the action of water, and, like the sulphochloride, may be partly distilled with water without decomposition. For complete decomposition it must be heated with water to 150° in a sealed tube for 4 hours. The products of decomposition are: free sulphur, hydrogen sulphide, phosphoric acid, and phosphorous acid, together with hydrochloric and hydrobromic acids. The quantity of free sulphur is exactly the half of that which is obtained by the decomposition of phosphorus sulphobromide.

PHOSPHORUS: OXIDES, OXYGEN-ACIDS, and OXYGEN-SALTS.

Hypophosphorous Acid, H^2PO^2 . This acid is generally said to be an uncrystallisable syrup. J. Thomsen, however, has obtained it as a snow-white crystalline mass, melting at 17.4° . The dilute solution, obtained by decomposing the barium salt with sulphuric acid, is first boiled down rapidly in a porcelain dish, and the evaporation completed in a platinum dish without ebullition, the temperature being allowed to rise gradually to 105° , at which most of the water can be driven off. The liquid is then filtered hot, and the heating continued gradually up to 130° . After 10 minutes at this temperature the acid is transferred to a bottle, and cooled below 0° . It exhibits strongly the phenomenon of superfusion, but crystallises when touched with a glass rod, or more readily by the addition of a crystal of the same acid (*Dent. Chem. Ges. Ber.* vii. 994).

Metallio Hypophosphites (Rammelsberg, *Chem. Soc. J.* [2], xi. 1; *Dent. Chem. Ges. Ber.* v. 492).—The *sodium salt*, $\text{H}^2\text{PO}^2 + \text{HFO}$, forms small undeterminable deliquescent crystals which become anhydrous at 100° . The *thallium salt*, H^2TlPO^2 , forms anhydrous crystals belonging to the rhombic system. The *ammonium salt*, $\text{H}^2(\text{NH}^4)\text{PO}^2$, the *barium salt*, $\text{H}^2\text{BaP}^2\text{O}^4 + \text{H}^2\text{O}$, and the *calcium salt*, $\text{H}^2\text{CaP}^2\text{O}^4$, also crystallise in the rhombic system. The *magnesium, zinc, nickel, and cobalt salts*, which contain 6 mols. water, form well-developed crystals belonging to the regular system.

All the hypophosphites, excepting those of thallium, calcium, cadmium, and lead,

contain water of crystallisation, which they give up completely and without decomposition at temperatures between 100° and 200° ; the nickel and cobalt salts, however, cannot bear without decomposition a temperature higher than 130° – 140° .

The decomposition of hypophosphites by heat does not in any case take place in the manner supposed by H. Rose (iv. 524), that is to say, into hydrogen phosphide, water, and a pyrophosphate, but in one of the two following ways:—

(1). The residue consists of a mixture of pyrophosphate and metaphosphate, and when dissolved in water leaves a small quantity of red phosphorus. The *alkali salts* (Na, Li, K), leave, on ignition, a residue consisting of 1 mol. $R^2P^2O^7$ and 1 mol. RPO^3 (R denoting a univalent metal), containing therefore, like the hypophosphite itself, $\frac{1}{2}$ at. metal to 2 at. oxygen. No water is given off. The hypophosphites of *magnesium, zinc, and manganese* yield a residue containing 2 mols. pyrophosphate to 1 mol. metaphosphate; in those of *strontium, calcium, cerium, and cadmium*, this ratio = 3 : 1; in the *lead salt*, 4 : 1; and in the *barium salt*, 6 : 1.

These modes of decomposition are represented by the following equations:

(2). The hypophosphites of *nickel and cobalt* leave, when ignited, a mixture of metaphosphate and phosphide, the latter of which gives the residue a black colour, and renders it almost insoluble in hydrochloric acid:

(3). *Ammonium hypophosphite* and *Uranyl hypophosphite* differ from all the other salts in their mode of decomposition by heat. The *ammonium salt* gives off ammonia, phosphine, hydrogen, and water, and leaves a residue consisting of 1 mol. pyrophosphoric and 2 mols. metaphosphoric acid:

The *uranyl salt*, which is yellow and sparingly soluble, decomposes with inflammation and explosive violence, giving off hydrogen and leaving a mixture of 3 mols. uranous pyrophosphate, 1 mol. uranous metaphosphate, and 1 mol. uranous monophosphide; thus, (U = 240):

The ratio of the number of atoms of phosphorus in the residue to the number which escape as gas in the decomposition of the several salts is as follows:

5 : 1	in the case of	Ni and Co
3 : 2	"	Na, Li, Mg, Zn, Mn.
4 : 3	"	Sr, Ca, Ce, Cd
5 : 4	"	Li, Pb
7 : 6	"	Ba,

but never 1 : 1, as formerly supposed.

The hydrogen of the hypophosphites behaves as follows. The sodium, potassium, thallium, magnesium, zinc, and manganese salts give off no water, the hydrogen being given off $\frac{1}{2}$ free, $\frac{1}{2}$ combined with phosphorus. All the other salts give off, together with hydrogen and phosphine, small quantities of water, the hydrogen of which amounts to $\frac{1}{2}$, $\frac{1}{3}$, or $\frac{1}{4}$ of the entire quantity of gas. Whether the evolved gas is spontaneously inflammable or not, depends altogether on accidental circumstances.

Reducing Power of Hypophosphorous and Phosphorous Acids.—The following experiments on the reducing power of these acids and their salts have been made by Rammelsberg (*Chem. Soc. J.* [2], xi. 13).

Phosphorous Acid and Silver Salts.—With excess of silver nitrate, 1 mol. H^2PO^3 reduces 1 at. silver, while hydrogen is set free:

Barium hypophosphite and Silver Salts.—1 mol. $H^2BaP^2O^7$, with an excess of silver nitrate, gave 5Ag, and with silver sulphate, 5.5 Ag. Admitting 6Ag, we should have $H^2BaP^2O^7 + 6AgNO^3 + 4H^2O = 2H^2PO^4 + 4HNO^3 + Ba^2NO^6 + 6Ag + 2H$.

The reducing power of the molecules H^2PO^3 and H^2PO^4 seems to be as 1 : 3.

Phosphorous Acid and Copper Salts.—An excess of H^2PO^3 decolorises the solution, cuprous oxide being formed. When the cupric sulphate is in excess, metallic copper

is separated, after boiling for some time, and 1 at. copper is reduced for every 3 at. phosphorus:

Barium phosphite is not changed by boiling with a solution of copper; when free sulphuric acid is added, a very small quantity of the metal is precipitated.

Hypophosphorous Acid and Copper Salts.—Hypophosphorous acid, heated with solution of cupric sulphate to 55° – 60° , forms a precipitate of cuprous hydride, Cu^2H^2 (Würtz, iv. 524). H. Rose (*Pogg. Ann.* lviii. 212) asserted that the reduction of copper by this acid was not attended with evolution of hydrogen. Rammelsberg finds that when barium hypophosphite is heated with excess of cupric sulphate, the precipitation of metallic copper takes place only at the boiling point of the liquid, and in the proportion 2 at. copper to 1 at. barium: consequently hydrogen must be evolved; further, that when free sulphuric acid is added, reduction begins below 100° , and the quantity of metal reduced is only half of what it was in the preceding case. The reactions in the two cases are:

The hydrogen is evolved with great rapidity.

Sodium hypophosphite with an excess of copper salt gives, Na : Cu = 1 : 1 at.; but the reaction requires continued boiling.

Phosphoric Acid. On the compound of phosphoric anhydride with boric anhydride, $\text{P}^2\text{O}^5 \cdot \text{B}^2\text{O}^3$, and on the reaction of phosphoric anhydride with boric chloride, see p. 207.

Estimation of Phosphoric Acid.—The two following methods are given by C. E. Munroe (*Sill. Am. J.* [3], i. 329).—1. To the boiling phosphate solution a weighed quantity of pure aluminium sulphate, previously dissolved, is added. A solution of mercuric chloride is then added, and finally pure sodium hydrate, until a precipitate of mercuric oxide is obtained which remains undissolved. To hasten the operation the precipitate is allowed to settle, and the supernatant liquid poured upon the filter. The gelatinous precipitate is then evaporated to complete dryness, filtered by the aid of a filter-pump, ignited, and weighed. The increase of weight over that of the alumina used is phosphoric oxide. The filter burns very slowly. Test analyses performed upon anhydrous disodic phosphate and crystallised ammonio-sodic phosphate gave very satisfactory results. The method appears, however, to be applicable with advantage only to the alkaline phosphates.

2. The second method is a modification of Rose's well-known mercury process. A boiling solution of the phosphate in nitric acid is precipitated with mercurous nitrate, a small quantity of mercuric nitrate is added, and then pure caustic soda, till a permanent red precipitate is obtained. The filtrate tested with molybdic acid does not exhibit a trace of phosphoric acid. The precipitate, consisting of mercurous phosphate and a little free mercuric oxide, is carefully separated from the filter, and intimately mixed in a porcelain crucible with a weighed quantity of cupric oxide; the filter is then laid upon the oxide and the whole ignited. The increase in weight of the crucible and cupric oxide gives the amount of phosphoric anhydride. By this method phosphoric acid may be separated from all bases except ferric and uranic oxides. From alumina the separation is perfect.

According to J. König (*Zeitschr. anal. Chem.* 1871, 473) the precipitation of phosphoric acid by *molybdic acid* is more or less prevented by ammonia salts when present in large quantity, the salts which act most injuriously in this respect being the oxalate and citrate. E. Richters (*ibid.* 469) also observes that certain salts, as well as free hydrochloric acid, interfere with the precipitation, but that ammonium nitrate promotes it in a very great degree; he therefore recommends a solution of this salt for washing the precipitated phosphomolybdate.

J. Parry (*Chem. News*, xxv. 279) recommends the use of an aqueous solution of ammonium molybdate, since in a strongly acid solution the precipitation is very slow.

Fresenius, Neubauer & Luck (*Zeitschr. anal. Chem.* x. 133) have examined the methods generally used for the estimation of phosphoric acid, with especial reference to the valuation of phosphatic manures.

1. Of the gravimetric methods, they find that the molybdenum method is the most accurate, provided it be performed in the following manner: The solution of 0.5 gram of the substance, in about 8 c.c. strong hydrochloric acid, is evaporated to dryness; the residue, after moistening with 2 c.c. hydrochloric acid, is dissolved in 10 c.c. nitric acid (sp. gr. 1.2); the solution diluted with water, filtered, and again evaporated; the

residue redissolved in 5 c.c. nitric acid; and the liquid digested for 12 hours at 40° with 150–200 c.c. of a solution of ammonium molybdate in nitric acid containing 5 pts. molybdic trioxide. When a sample of the supernatant liquid no longer gives any turbidity with the molybdic acid solution, the precipitate is collected on a filter, washed with 100 pts. of the molybdic acid solution, 20 pts. nitric acid, and 80 pts. water, then dissolved in the smallest possible quantity of aqueous ammonia; the solution, approximately neutralised with hydrochloric acid, is precipitated with a mixture of magnesium sulphate, ammonium chloride, and ammonia; and the precipitated ammonium-magnesium phosphate is washed with ammonia-water, dried, and ignited in the usual way.

The bismuth, uranium, lead, mercury, and tin methods, are admissible only when iron and aluminium are absent; in the presence of either of these bodies, the methods in question cannot be used without considerable modifications, which rob them of all their special advantages. The use of tartaric or citric acid, to keep iron and aluminium in solution during the precipitation of phosphoric acid by magnesia, does not yield very satisfactory results, since basic magnesium tartrate or citrate is often precipitated with the phosphate, and because the solubility of the ammonio-magnesium phosphate is increased by the presence of ammonium tartrate or citrate.

The volumetric uranium method, as ordinarily used, is trustworthy only when alkalis and magnesia are the only bases present. If citric acid is used to keep iron and aluminium in solution during the titration, some uncertainty is introduced, as free citric acid increases the solubility of uranium phosphate, and thus tends to give low results, while ammonium citrate, by diminishing the delicacy of the ferrocyanide-test, tends to give high results. If lime is present, the results are apt to be low, since calcium phosphate partially separates from an acetic acid solution on heating, and thus a portion escapes the action of the uranium. This error may, however, be got rid of by reversing the process, and adding a cold acetic solution of the phosphate to a hot solution of uranium, till the ferrocyanide-test just ceases to act.

According to W. Jani (*Chem. Centr.* 1871, 230) the accuracy of the volumetric uranium method is not affected by the presence of ammonium salts, but an excess of acetic acid or an acetate seriously affects the result. It is best, therefore, to neutralise the free acid present, not by means of sodium acetate, but by carefully adding ammonia or soda till the solution is slightly alkaline, and then a few drops of acetic acid. With this precaution the results obtained by titration with uranium solution agree with those of the best gravimetric methods.

C. Schumann (*Zeitschr. anal. Chem.* 1872, 382) uses a solution of *uranic nitrate* for the titration in preference to the acetate, because the appearance of the reaction with potassium ferrocyanide is then more sharply marked and the solution may be kept without alteration, especially if acidulated with a few cubic centimeters of nitric acid, whereas the acetate is very apt to deposit a basic salt. To avoid, however, the presence of free nitric acid, when a large quantity of uranium solution has to be added, as in the analysis of phosphates very rich in phosphoric acid, Schumann mixes the phosphatic solution with a sufficient quantity of sodium acetate, this quantity bearing the same proportion to the entire liquid as in the titration (according to Schumann, 20 c.c. sodium acetate to 50 c.c. of the phosphoric acid solution). The error arising in the analysis of calcareous phosphates from the precipitation of calcium phosphate by long boiling is avoided in the method of Fresenius, Neubauer & Luck, by reversing the process and titrating the uranium solution warmed in the water-bath with the phosphoric acid solution (see above). Schumann avoids it by the employment of the so-called *pre-titration*—that is to say, by first determining the quantity of uranium solution required for about 10 c.c. of the phosphoric solution. This renders it possible, in the subsequent titration of a larger volume of the same liquid, to add at once the exact quantity of the uranium solution required, within a few cubic centimeters, so that prolonged boiling may be dispensed with. The titration is conveniently performed in a flask which is heated, with frequent agitation, over a free flame, and the addition of the uranium solution is discontinued as soon as two drops of the liquid spread upon a porcelain plate, with a drop of ferrocyanide solution let fall as nearly as possible in the middle, form a distinct ring of uranium ferrocyanide which does not disappear on renewed boiling.

Among gravimetric methods, Schumann finds that the determination as *ammonio-magnesium phosphate* gives perfectly trustworthy results, provided the following directions are observed. The ammonio-magnesium phosphate must be kept, both during precipitation and during washing, in an ammoniacal liquid containing at least 2.5 grms. of ammonia in 100 cubic centimeters. In an ammoniacal liquid of this strength the ammonio-magnesium phosphate is quite insoluble, so that the correction of 0.001 grm. of magnesium pyrophosphate for every 54 c.c. of liquid, formerly recommended by Fresenius, may be dispensed with.

The exactness of the composition of the precipitated ammonio-magnesium phosphate was demonstrated by taking two equal quantities of a solution of disodic phosphate, evaporating one to dryness, igniting, and weighing the residue of sodium pyrophosphate; then precipitating the other as ammonio-magnesium phosphate, igniting the precipitate, and weighing the resulting magnesium pyrophosphate. The quantities of phosphoric acid calculated from these two determinations were almost exactly the same, viz. 0.1171 gram from the first and 0.1167 from the second. A second precipitation of the ammonio-magnesium phosphate is therefore superfluous, and indeed injurious, inasmuch as the dissolved precipitate is not completely reprecipitated by ammonia alone.

The excess which sometimes occurs in the estimation of phosphoric acid as magnesium pyrophosphate, in consequence of the simultaneous precipitation of basic magnesium salts, may be avoided by using only a slight excess of magnesia mixture, the solution being brought down to a determinate volume, and the quantity of magnesia mixture required for each precipitation approximately calculated. The liquid should be made ammoniacal before the addition of the magnesia mixture, unless the ammonia used is very dilute, and the precipitate must be washed with aqueous ammonia of 2.5 p.c. till a few drops of the wash-water do not exhibit the slightest turbidity on addition of silver nitrate. In case the liquid has acquired a high temperature, in consequence of chemical action taking place within it—as, for example, when a molybdenum precipitate is dissolved in strong ammonia, and the ammonia neutralised with hydrochloric acid—it must be left to cool before precipitation. There is no occasion to boil the magnesia precipitate for more than 12 hours, unless the quantity of phosphoric acid present is extremely small.

According to L. Brunner (*Zeitschr. anal. Chem.* 1872, 30), a solution of magnesium sulphate mixed with a certain quantity of sal-ammoniac gives with ammonia a precipitate of magnesium hydrate, when the temperature of the solution exceeds 60°. This circumstance must be taken into account in the analysis of artificial manures, when the phosphoric acid has to be determined in the filtrate from a precipitate of calcium oxalate which has been washed with boiling water.

E. W. Parnell (*Chem. News*, xxiii. 145) points out the insolubility of ammonio-magnesium phosphate in an ammoniacal liquid containing excess of magnesia. He recommends that the precipitation be performed in a hot dilute ammoniacal solution, in which case no magnesia will be carried down with the precipitate.

To determine phosphoric acid in presence of aluminium and iron (which preclude the immediate use of the uranium method), G. Villo (*Compt. rend.* lxxv. 344) mixes the hydrochloric acid solution with citric acid and excess of ammonia, and precipitates with excess of *magnesium chloride*, dissolves the precipitate in a small quantity of nitric acid, and estimates the phosphoric acid volumetrically with uranic acetate. According to his observations, the excess of magnesium chloride used for the precipitation counteracts the solvent action of the ammonium citrate, and more especially of the calcium citrate, on the ammonium-magnesium phosphate.

Analysis of Phosphorite.—When nitric acid acts on a phosphorite, the greater part of the iron remains undissolved, and with it a small portion of the phosphoric acid. Cold 5 p.c. sulphuric acid dissolves very little iron, and all but 0.1 p.c. of the phosphoric acid. Hydrochloric acid, however, takes up the whole of the phosphoric acid and iron; for the analysis therefore it is best to dissolve the phosphorite in hydrochloric acid.

For the determination of the phosphoric acid, Fresenius, Neubauer and Luck give the preference to the molybdenum method in all cases where scientific accuracy is desired; but for commercial purposes, the following method, which takes up much less time, and is sufficiently exact, may be advantageously employed.

110 c.c. of 5 p.c. sulphuric acid are taken; 5 grams of the very finely-ground phosphorite are placed in a mortar, rubbed slowly with some of the acid till brought to a soft paste, then diluted with water, and the suspended matter is decanted into a flask graduated for 253 c.c., the residue being treated as before. When both phosphorite and acid have been thus brought into the flask, the whole is agitated from time to time during four hours. The flask is next filled up to the mark, and then contains 250 c.c. of liquid (the solid matter occupying 3 c.c.); the solution is filtered; 100 c.c. of the filtrate are placed in a flask graduated for 200 c.c., treated with excess of caustic soda, and then with acetic acid, till it ceases to diminish the precipitate; the flask is then filled to the mark, and the solution after standing in the cold is filtered; the precipitate is weighed, and reckoned as ferric phosphate. The phosphoric acid in the solution is determined by the improved volumetric uranium method already mentioned (p. 988). The known quantity of uranium acetate employed is mixed with sodium acetate and acetic acid, and kept at a temperature of 30°–40° during the titration.

Analysis of Superphosphates (Fresenius, Neubauer & Luck, *loc. cit.*)—In lixiviating a superphosphate for the purpose of dissolving out the soluble phosphate, the material should not be very finely divided, as in that case the quantity of phosphoric acid will come out rather too high. The lixiviation is best performed by the method given by Fresenius in his *Anleitung zur quantitativen Analyse*. The phosphoric acid may then be determined by the molybdenum method or by the method last described.

Superphosphates often contain 'reduced phosphates'—that is to say, phosphates in which part of the soluble phosphoric acid has returned to the insoluble state, in consequence, according to some authorities, of the action of monocalcic phosphate on oxide of iron or alumina; according to others, from the action of the same body on undecomposed tricalcic phosphate. For the estimation of these reduced phosphates, sodium bicarbonate and ammonium oxalate have been recommended. To test the accuracy of the results obtained by their use, experiments were made on the precipitate obtained by adding excess of ordinary sodium phosphate to calcium chloride (chiefly dicalcic phosphate), which may be taken as a type of reduced phosphate. Prolonged boiling with sodium bicarbonate removes only about half the phosphoric acid present in this substance; half-an-hour's boiling with ammonium oxalate removes nearly all the phosphoric acid; but as ammonium oxalate also acts energetically upon natural phosphorite, the results obtained with it cannot be depended upon. A solution of neutral ammonium citrate, sp. gr. 1.00, was found, however, to answer the purpose required; it had practically no action on natural phosphorite, and decomposed the precipitated phosphate almost completely.

To estimate the reduced phosphate, two portions of the superphosphate, each weighing 2 grams, are lixiviated with water. In one of the residues thereby obtained, the unattacked and reduced phosphoric acid are determined together (*a*); the other is treated with ammonium citrate, as above described, to remove the reduced phosphoric acid; and in the residue thus obtained the amount of phosphoric acid (*b*) is determined after ignition with sodium carbonate, in the manner described for the analysis of phosphorite. This gives the amount of unattacked phosphoric acid, and the difference between *a* and *b* gives the quantity of reduced phosphoric acid in the superphosphate.

R. Warington (*Chem. Soc. J.* [2], ix. 584) finds that the exhaustion of superphosphates with hot water yields, according to circumstances, sometimes a larger, sometimes a smaller, proportion of soluble phosphates than exhaustion with cold water. If the superphosphate contains soluble aluminium salts, it will yield less soluble phosphate when boiled with water than when exhausted with cold water: this is shown by the fact that alum added to a cold solution of superphosphate produces no change, but on applying heat aluminium phosphate is precipitated. Ferric salts, on the other hand, give an immediate precipitate in the cold. Most superphosphates contain traces of soluble aluminium salts; those prepared from aluminous phosphates may contain a considerable quantity; the amount, however, depends much on the manner of manufacture. The solutions of such superphosphates in cold water become turbid on boiling.

It appears from the above that the soluble phosphate should always be extracted with cold water. The residue then yields a further trifling amount of phosphoric acid on boiling, arising probably from decomposition of reduced phosphates. The best method of extracting soluble phosphate is to take 10 grams of the superphosphate and elutriate them in a mortar with 1 litre of cold water. The water and suspended matter are poured into a bottle and shaken at frequent intervals during three hours. 100 c.c. of the solution correspond with 1 gram of the superphosphate.

The soluble phosphate is usually estimated by precipitation with ammonia, with or without calcium chloride, according to the proportion of lime in the solution. This method is liable to several errors; the results should be checked by some other method.

The soluble phosphate may be accurately estimated by uranium acetate if alumina be absent, or if alumina has been previously removed as phosphate by ammonium acetate.

A method available under all circumstances is to precipitate the solution of superphosphate with excess of ammonium oxalate, and treat the filtered liquor containing the alumina and phosphoric acid with citric acid, ammonia, and magnesia mixture, determining the phosphoric acid as magnesium pyrophosphate.

The insoluble phosphates in superphosphate are generally estimated much above the truth. It is best to determine the total phosphate by one operation, and then estimate the insoluble by deducting the soluble phosphate. The total phosphate may be determined by solution in hydrochloric acid, and precipitation from a cold dilute solution with a small excess of ammonia, just sufficient to turn turmeric red. If, however, the superphosphate contains iron or aluminium, the hydrochloric solution should be neutralised as far as possible without producing a precipitate, and then treated with

excess of ammonium oxalate, and subsequently with citric acid and magnesia mixture, as already described.

G. Ville (*Compt. rend.* lxxv. 334) describes a simple apparatus for filtering precipitates under pressure in the estimation of phosphoric acid on natural phosphates.

Birnbaum a. Chojnacki (*Zeitschr. anal. Chem.* 1870, 203) discuss the several methods in use for the estimation of phosphoric acid in phosphorites, and give the preference to a modification of Chancel's bismuth method (iv. 543).

P. Gräsert (*ibid.* 356) describes the process used for estimating phosphoric acid in the Lahn phosphorites, which consists essentially in the application of the volumetric uranium method.

Joulié (*Moniteur Scientifique* [3], ii. 213-232) publishes Researches on the Estimation of Phosphoric acid in all products relating to Agriculture and Physiology.

Comparative experiments on the different methods of estimating phosphoric acid and separating it from bases have also been published by R. Schweizer (*Zeitschr. anal. Chem.* 1870, 84), and by J. Janowsky (*ibid.* 1872, 152-167).

A modification of the method of Reynoso and of Reissig (iv. 644), depending on the use of stannic oxide, is described by W. C. Williams (*Chem. Soc. J.* [2], viii. 383).

Metallo Phosphates. *Preparation of Crystallised Phosphates.*—W. Skey (*Chem. News*, xxii. 61) has prepared several phosphates in the crystalline state by mixing solutions of the corresponding metallic salts with a soluble phosphate, in such proportion that the mixture shall retain an acid reaction. If the precipitate forms slowly, it may separate at once in the crystalline state; if it appears immediately, it is gelatinous, but becomes crystalline after a longer or shorter time. In this manner the following crystallised phosphates have been obtained, most of them resembling native minerals: zinc phosphate (hopcite), $\text{Zn}^2\text{P}^2\text{O}^8 + 5\text{H}^2\text{O}$, and cadmium phosphate, not known as a natural mineral; calcium phosphate, $\text{Ca}^2\text{H}^2\text{P}^2\text{O}^8 + 3\text{H}^2\text{O}$, rhombic, isomorphous with pharmacolite, having an acid reaction; chromic phosphate, with $24\text{H}^2\text{O}$, having the constitution of delvauxin and the colour of chrome-alum; silver phosphate, crystallised only from solution in acetic acid; barium phosphate and strontium phosphate. The phosphates of copper, nickel, cobalt and iron were not obtained in the crystalline state, but they form double salts with the phosphate of magnesium and ammonium. Zinc phosphate forms crystalline compounds with the phosphates of cobalt and nickel.

Action of Sulphurous Acid on Phosphates (Gerland, *J. pr. Chem.* [2], iv. 97).—Different phosphates are variously acted on by sulphurous acid in aqueous solution: some are simply dissolved, while others are completely decomposed, a sulphite being formed, and phosphoric acid going into solution. From some compounds sulphurous acid withdraws a part of the base, so that from a basic compound a neutral or acid salt is produced; upon others, viz., tricalcic phosphate, sulphurous acid acts in a way different from any of the foregoing.

1. *Tricalcium phosphate* is easily soluble in sulphurous acid. Concentrated solutions are decomposed at temperatures above 18° , forming mono- and dicalcium-phosphate and calcium sulphite. Both concentrated and dilute solutions are decomposed into dicalcium-hydrogen phosphate and calcium sulphite by alcohol, when placed, at ordinary temperatures, in a vacuum, or more quickly when boiled under diminished atmospheric pressure. But by quickly heating and boiling at the ordinary pressure, crystals are deposited consisting of tricalcium phosphato-sulphite, $\text{Ca}^2\text{P}^2\text{O}^8\text{SO}^2 + 2\text{H}^2\text{O}$.

The same substance is deposited as a white crystalline precipitate when sulphurous acid is passed into a watery solution in which tricalcium phosphate is suspended. After complete solution of the phosphate is effected, the liquid is quickly boiled, and the precipitate collected. It differs from the above-mentioned mixture of dicalcium phosphate and calcium sulphite by its great stability; it may be heated to 110° without decomposition, but at a somewhat higher temperature it is broken up, and gives off watery vapour, mixed with sulphurous and sulphuric acid vapour and sulphur. It possesses disinfectant properties in a marked degree; it is stable, has no smell, is tasteless, does not affect linen or woollen cloths, and is obtained in a very convenient form, as a heavy, white, dry powder. A small quantity mixed with decaying animal matter at once removes its bad odour. Although unchanged in pure air, it undergoes slow oxidation when placed in air containing decomposing animal matter. The corresponding compounds of the other metals have not been obtained.

2. *Dicalcium-hydrogen phosphate* dissolves easily in sulphurous acid, the phosphate being again obtainable from this solution, unchanged. All these solutions retain the gas which they have absorbed with great energy, but the basic do so more energetically than the neutral phosphates.

3. *Basic and neutral magnesium phosphate* and *magnesium-ammonium phosphate* are easily dissolved by water containing sulphurous acid, the first two without decomposition; the last, when in excess, gives neutral magnesium phosphate.

4. *Basic and neutral manganese phosphate* behave in a similar manner to the magnesium phosphates. In the cold the solutions yield crystals composed chiefly of the neutral phosphate; by boiling, the crystalline basic phosphate is precipitated.

5. *Copper phosphate* is only slightly dissolved by sulphurous acid solutions. At ordinary temperatures crystals of cuproso-cupric sulphite are deposited; by boiling, a copper phosphate, probably of the same composition as the original phosphate, is obtained.

6. *Uranium phosphate* is but slightly soluble in sulphurous acid, being deposited again unchanged.

7. *Trisodium phosphate* takes up sulphur dioxide very readily; and alcohol separates sodium phosphate from the solution. The crystals saturated with sulphur dioxide form a solution which, on standing, separates into two distinct layers, which on being shaken, unite to form a homogeneous liquid.

8. *Bismuthic, stannous, stannic, and metastannic phosphates* are in no way acted upon by sulphurous acid.

9. *Silver, lead, and barium phosphates* are acted upon by an aqueous solution of sulphurous acid in the same way as by other strong acids, sulphites and free phosphoric acid being formed.

Aluminium Phosphates.—*Amblygonite* and *Montebrazite* (Descloizeaux, *Compt. rend.* lxxii. 306; lxxiii. 1247; lxxv. 114; lxxvi. 319. Pisani, *ibid.* lxxiii. 1470; lxxv. 79. Rammelsberg, *Deut. Chem. Ges. Ber.* v. 78. See also *Chem. Soc. J.* [2], ix. 892; x. 126, 468, 793; xi. 481, 1113). The lithio-aluminic fluo-phosphates found at Penig in Saxony, and at Hebron in the state of Maine (U.S.), have hitherto been regarded as identical, and designated as *amblygonite*. In 1871, however, a mineral of similar composition, but supposed to differ from *amblygonite* in the relative proportions of its constituent elements, and in its optical properties, was found in the stanniferous strata of Montebraz (Creuse), and was named *montebrazite*. Subsequently this mineral was analysed by Pisani, v. Kobell, and Rammelsberg, who concluded that it was identical in composition with the *amblygonite* of Saxony; that from Hebron had not then been analysed. More recently, however, Pisani has analysed the American mineral, and finds that it is a hydrated fluo-phosphate of aluminium and lithium not containing sodium, whereas the Saxon mineral is an anhydrous phosphate of aluminium, lithium, and sodium; and Descloizeaux has shown that the two minerals differ in their optical properties. Further, it is now known that both these minerals occur in the stanniferous strata of Montebraz, though in very different quantities, the more abundant being identical with the sodio-lithio-aluminic fluo-phosphate of Penig, the less abundant with the lithio-aluminic fluo-phosphate of Hebron; and it is proposed by Descloizeaux and Pisani to designate the former by the old name of *amblygonite*, the latter by that of *montebrazite*.

Both minerals are triclinic. *Amblygonite* occurs in laminar masses, opaque or more or less translucent, and having a dull white or faint violet colour. It cleaves imperfectly, but with about equal facility, in two directions inclined at an angle of about $105^{\circ} 44'$, the reflected images from the two cleavage-surfaces differing slightly in brightness; also in two other directions making respectively with the two former a very obtuse angle of nearly 162° . These four cleavages determine the faces of the primary parallelepiped $p\ m\ t$, or $OP.\ \infty P.\ \infty P'$, or 001 110 $\bar{1}10$, having its right upper edge replaced by a truncation-face i' . The angles of these faces are—

$$mt = 151^{\circ} 4';\ pm = 105^{\circ} 44';\ pt = 95^{\circ} 20';$$

$$i'm = 96^{\circ} 15';\ i't = 95^{\circ} 20';$$

$$pi' = 152^{\circ} 57' \text{ (calc.)},\ 152^{\circ} 10' \text{ (obs.)}$$

Montebrazite occurs at Montebraz, in small quantity, in greenish-white laminar masses, much more transparent than *amblygonite*; at Hebron also in laminar masses and in distinct four-sided prisms. Sp. gr. of the Montebraz mineral = 3.010; of that from Hebron, 3.029. It exhibits the three principal cleavages p, m, t , the angles between which are—

$$mt = 135^{\circ} \text{ to } 136^{\circ};\ pm = 105^{\circ};\ pt = 89^{\circ} \text{ to } 89^{\circ} 11'.$$

The angle pm is nearly the same in both minerals; but the other angles differ widely in the two.

In *amblygonite* the optic axes are situated in a place which divides into two very unequal parts the acute angle $pm = 74^{\circ} 16'$. In the *montebrazite* of Hebron, on the other hand, the plane of the optic axes is situated in the obtuse angle pm , and traverses the edge t , but is not quite normal to m , since it gives angles of 82° with m .

and 23° with *p*. The character of the coloured rings shows that in montbrasite, both from Montebbras and from Hebron, there coexists with the horizontal a well-marked inclined dispersion, and these are peculiar to the crystals of the triclinic system. In amblygonite from Montebbras the appearance of the bars traversing the central ring of each system indicates very distinctly a *twisted* dispersion, which is also characteristic of the triclinic system.

Amblygonite melts easily in the flame of a spirit-lamp, without decrepitation, but with slight tumefaction, to a white opaline glass. To the blow-pipe flame it imparts a reddish yellow colour, due to the occurrence of sodium and lithium in about equal proportions. The optical properties of the amblygonite of Montebbras agree exactly with those of the Saxon mineral.

Montebbrasite melts before the blowpipe to a white enamel, and colours the flame a fine red, without any yellow tinge. In the spectroscopic it exhibits the lithium line. Heated in a tube it decrepitates more or less strongly (especially that of Montebbras), giving off water which has an acid reaction and corrodes the glass strongly (Pisani).

The difference of chemical composition of amblygonite and montebbrasite is shown by the following analyses :—

	Amblygonite						Montebbrasite	
	From Montebbras			From Penig			From Montebbras	From Hebron
	Pisani	v. Kobell	Rammelsberg	Rammelsberg	Pisani			
Fluorine	8.20	10.40	9.00	10.06	8.11	9.44	3.80	5.22
Phosphoric anhydride	46.15	46.85	45.91	48.55	47.58	48.00	47.15	46.65
Alumina	33.82	37.60	35.50	36.36	36.88	36.26	36.90	36.00
Lithia	8.10	9.60	6.70	7.06	6.68	6.68	9.84	9.75
Soda	2.28	0.59	5.30	0.93	3.29	3.29	—	—

Lime	—	—	0.50	—	—	—	—	—
Manganese oxide	0.40	—	—	—	—	—	—	—
Silica	—	—	0.60	—	—	—	—	—
Water	1.10	0.14	0.70	—	—	—	4.75	4.20
	100.05	105.18	104.21	104.26	102.97	104.10	102.44	101.82

Von Kobell (*Jahrbuch f. Mineralogie*, 1873, 317) considering that there is some confusion in the use of the name montebbrasite applied by Descloizeaux to the hydrated lithio-aluminic fluo-phosphate occurring at Montebbras and at Hebron, proposes to discard this name altogether and designate the mineral in question as Hebronite. He has examined more particularly a specimen of hebronite from Auburn in Maine. This variety colours the blowpipe strongly reddish-yellow, the red colour of the lithium being altered by the small quantity of sodium contained in the mineral. The hebronite of Auburn, and also that of Paris in Maine, exhibit a rather strong greyish phosphorescence when heated. The specific gravity of the Auburn hebronite is 3.06. Its analysis gave—

P ² O ⁵	Al ² O ³	Li	Na	F	H ² O
40.00	37.00	3.44	0.79	5.50	4.50 = 100.23

agreeing with the formula : $3(\text{Al}^2\text{O}^3 \cdot \text{P}^2\text{O}^5) + \text{Li}^2\text{F}^2 + 2\text{H}^2\text{O}$.

Calcium Phosphates.—1. *Native*, from Canada, occurring in a bed about five meters thick, partly in crude masses (A), partly in prismatic crystals (B), has been analysed by R. Hutton (*Chem. News*, xxi. 150). Both varieties are partly green and bluish-green, partly red.

Ca ² P ² O ⁵	CaF ²	CuCl ²	CaCO ³	Fe ² O ³	H ² O	Sand	Sp. g.
A. 88.61	7.22	0.06	4.47	—	0.08	0.10 = 98.54.	3.142
B. 90.82	5.70	0.14	0.38	0.40	0.32	0.10 = 97.80.	3.166

On the wide diffusion of apatite as a constituent of eruptive rocks and basalts, see F. Zirkell (*Jahrbuch f. Mineralogie*, 358, 801; *Jahresh. f. Chem.* 1870, 1343, 1362). *Francolite*.—This name is given by Maskelyne a. Flight (*Chem. News*, xxii. 280) to a mineral from Cornwall allied to staffelite (1st Suppl. 1037), occurring in aggregates

and intersecting twins of the hexagonal form $\infty P \cdot mP$, wherein mP denotes a very obtuse pyramid. Analysis gave numbers agreeing approximately with the formula: $5Ca^{2}P^{2}O^{6} \cdot CaCO^{3} \cdot CaF^{2}$

$Ca^{2}P^{2}O^{6}$	CaF^{2}	$CaCO^{3}$	$Fe^{2}O^{3} \cdot Mn^{2}O^{3}$	$Na^{2}O$	$H^{2}O$
83.261	7.683	5.104	0.913	0.694	1.593 = 99.248

On the question whether staffelite is a distinct mineral species, see *Jahresb. f. Chem.* 1870, 1317.

For analysis of phosphatic concretions containing calcium phosphates from various localities, see *Jahresb. f. Chem.* 1870, 1316; 1871, 1219.

On the occurrence and formation of the phosphorite found on the Dniester in Russian Podolia, Galicia and Buckowina, see Schwachhöfer (*Wien. Akad. Ber.* lxiii, [2], 809; *Chem. Soc. J.* [2], x. 56). On the great phosphoritic zone of Russia, see Grewingk (*Jahrbuch. f. Mineralogie*, 1871, 757; *Chem. Soc. J.* [2], x. 58).

Bone Phosphates.—To determine the constitution of the calcium phosphate of bones, C. Aebv (*J. pr. Chem.* [2], v. 308; vi. 169) has analysed bones calcined by a natural process, as they occur in caves and in the form of fossil ivory in diluvial deposits. According to his analysis, such bones consist of 1 mol. orthophosphate, $3CaO \cdot P^{2}O^{5}$, $\frac{1}{2}$ mol. water of crystallisation, $\frac{1}{2}$ mol. basic water, $\frac{1}{2}$ mol. lime in excess, and $\frac{1}{2}$ mol. carbon dioxide as an essential constituent. The carbon dioxide which exists in this form may be driven off, together with water of crystallisation, by heating to 450° , and cannot be restored by treatment with ammonium carbonate. After ignition and addition of ammonium carbonate, the weight and composition of the bone phosphates are the same as after six hours' heating to 450° .

Calcium Phosphates formed by Precipitation.—E. Reichardt (*Zeitschr. anal. Chem.* 1873, 275) finds that when a dilute solution of calcium chloride is precipitated by a small quantity of sodium phosphate, a precipitate which dissolves on agitation is produced, the redissolution being apparently due to the presence of carbonic acid in the water. A further addition of sodium phosphate reproduces the precipitate, and it may be again dissolved by passing a current of carbonic acid through the mixture. After some repetitions of this operation, the liquid deposits shining crystals, which were found to be identical with Boedeker's tetra-hydrated dicalcic orthophosphate, $Ca^{2}H^{2}P^{2}O^{6} \cdot 4H^{2}O$.

When this compound is boiled with water, it is partially decomposed; the portion remaining undissolved gave results agreeing with the formula, $Ca^{2}P^{2}O^{6} \cdot Ca^{2}H^{2}P^{2}O^{6} \cdot 3H^{2}O$, and the solution yielded, on evaporation, a residue which, after ignition, gave numbers corresponding with the formula $4CaO \cdot 3H^{2}O^{2}$. This substance dissolves in 3325.5 pts. of water. See also W. C. Davis (*Chem. Soc. J.* [2], v. 673).

Solubility in Carbonic Acid Water.—C. P. Williams (*Chem. News*, xxiv. 306) has determined the solubility of various calcium phosphates used in agriculture. The pulverised material was diffused through a very large quantity of water, carbon dioxide was passed through the liquid for five or six hours at a temperature 60° to 70° F., and the quantity of phosphoric acid in the filtrate was determined in the ordinary way after supersaturation with nitric acid.

	$3CaO \cdot P^{2}O^{5}$ per cent.	1 pt. $3CaO \cdot P^{2}O^{5}$ re- quires of Carbonic Acid Water

Guano phosphate from Orchilla	49.87	8,008

R. Warrington (*Chem. Soc. J.* [2], ix. 80) has made experiments on the solubility of bone-ash when repeatedly treated with carbonic acid water. The materials used were a commercial bone-ash containing 33.68 p.c. $P^{2}O^{5}$, and a pure bone-ash containing 39.55 p.c. The ash was drenched with water, and carbon dioxide was passed into the water for 16 to 24 hours on three or more successive days, the ash being stirred from time to time. The water was then poured off and analysed, and the residue left each time was treated in the same manner for the preparation of the following solution.

* This bone-ash probably contained $CaO \cdot 2H^{2}O \cdot P^{2}O^{5}$.

I. Experiments on the Solubility of Commercial Bone-ash.

The whole effect produced by the carbonic acid water upon the pure bone-ash appears to have consisted in the removal of but a small quantity of the phosphoric acid and lime (the latter in somewhat larger proportion than the former), while nearly the whole of the magnesia was taken up. The magnesium salts in bone-ash appear, indeed, to be much more soluble than the calcium salts. Taking the mean of the last four experiments in the second table as representing the permanent solubility of the phosphates of the pure bone-ash, we have a solubility of 0.675 P₂O₅ in 10,000 pts. of carbonic acid water; and reckoning the phosphoric acid as tricalcic phosphate, the solubility of this phosphate in carbonic acid water is 1 pt. in 6788.

Copper Phosphates.—Rammelsberg (*Pogg. Ann.* lxxviii. 383) found that, on dropping 3 mols. cupric sulphate into a hot solution of 2 mols. ordinary sodium phosphate, a precipitate is formed having the composition 2[(CuO)²P₂O₅] + CuO.P₂O₅ + 3H₂O. According to J. Weinck (*Ann. Ch. Pharm.* clvi. 57), the precipitate thus formed contains soda. In the perfectly washed precipitate dried at 100°–110°, he found, as a mean, 38.32 p.c. P₂O₅, 40.45 CuO, 8.84 Na₂O, and 6.75 H₂O, giving approximately the proportion 4P₂O₅ : 9CuO : 2Na₂O.* He regards this substance as a mixture of several compounds, and suggests that other phosphates obtained by precipitation with sodium phosphate may also contain soda.

Magnesium Phosphates.—According to O. Popp (*Zeitschr. f. Chem.* 1870, 305), ammonium-magnesium phosphate, when heated, always exhibits the well-known appearance of ignition, provided it is free from foreign admixtures. The glow may, however, be weakened, or may not take place at all, if the phosphate contains calcium salts or other salts of magnesium, and especially if it contains a small quantity of silica. The glow takes place at a rather high temperature when all the water and ammonia have been already driven off, so that weighings before and after its appearance show no difference. This glow-phenomenon cannot be due to the conversion of the phosphoric into pyrophosphoric acid, since precipitated magnesium pyrophosphate, Mg²P₂O₇ + 6H₂O, likewise glows when raised to a strong red heat. Popp considers that it is caused by the passage of the substance from the crystalline to the amorphous state—in fact, by fusion; and that it must be regarded as analogous, though in the contrary direction, to that which takes place when vitreous amorphous bodies (amorphous arsenious oxide and fused boric oxide) assume, under certain conditions, the crystalline

* The circumstance that this precipitate contains 11 mols. base to 4 mols. phosphoric acid, whereas the sodium phosphate contains only 8 mols. base to 4 mols. acid, explains the fact previously noticed by Rammelsberg, that the nitrate has an acid reaction. Weinck found, in contradiction to Rammelsberg, that this nitrate is precipitated by a small quantity of cupric sulphate (*Jahresb.* 1870, 385).

form. Arsenate of magnesium and ammonium does not glow when heated, apparently because the magnesia set free at the same time prevents the fusion of the arsenate. The incandescence which certain hydrated metallic oxides, as chromic oxide, ferric oxide, &c., exhibit when heated, admits also, according to Popp, of a similar interpretation, which at the same time serves to account for the great indifference of the resulting anhydrous oxides.

Silver Phosphates.—According to E. N. Horsford (*American Chemist*, i. 284) triargentic phosphate, heated to redness with pure sand, is converted into the corresponding metaphosphate.

Sodium Phosphates.—When sodium pyrophosphate is fused with 1 mol. of boric oxide, a phosphoborate of sodium is produced, which, by the action of water or alcohol, is decomposed into boric acid and ordinary sodium phosphate. If the pyrophosphate be heated with oil of vitriol till vapours of sulphuric acid are no longer evolved, and the product be then dissolved in water acidulated with phosphoric acid, the solution on evaporation yields brilliant plates of a salt having the constitution $\text{Na}^+\text{SO}^+\text{HPO}^-\text{H}^+\text{O}$:

An acid phosphate will give a similar result. The phospho-sulphate is permanent in air. It loses 1 mol. of water at 200° , and the second only at a red heat, when it is decomposed into sulphuric acid and pyrophosphate. Pure water resolves it into phosphoric acid and a sulphate.

On treating metaphosphoric acid with 2 mols. of sulphuric acid, a syrupy uncrystallisable liquid is produced, decomposed instantly by water into orthophosphoric and sulphuric acid. The solution is no longer precipitated by albumin. Hence we may conclude that a double acid corresponding with sodium phosphosulphate has been formed (Prévault, *Compt. rend.* lxxiv. 1249).

On the amount of Heat evolved in the Solution of Sodium Phosphate containing different Proportions of Water of Crystallisation, see Pfaunder (*Deut. Chem. Ges. Ber.* iv. 773; *Chem. Soc. J.* [2], ix. 1131).

Thallium Phosphates.—Observations on the isomorphism of these salts with the phosphates of the alkali-metals have been made by Rammelsberg (*Deut. Chem. Ges. Ber.* iii. 276). He thinks it probable that acid thallious phosphate, to which Lamy a. Descloizeaux (*Ann. Chim. Phys.* [4], xvii. 310) assigned the formula $2\text{Tl}^+\text{HPO}^-\text{H}^+\text{O}$, has really the composition $\text{Tl}^+\text{HPO}^-\text{H}^+\text{O}$, analogous to that of the sodium salt, $\text{Na}^+\text{HPO}^-\text{H}^+\text{O}$, with which it is isomorphous. *Monothallious orthophosphate*, $\text{Tl}^+\text{H}^+\text{PO}^+$, is, according to Rammelsberg, isomorphous with the ammonium salt, $(\text{NH}^+)\text{H}^+\text{PO}^+$. Lamy a. Descloizeaux describe a compound of thallious phosphate with ammonium phosphate containing $(\text{NH}^+)\text{PO}^+$, $(\text{NH}^+)\text{TiPO}^+$, and isomorphous with the ammonium salt, $(\text{NH}^+)\text{H}^+\text{PO}^+$. The compound prepared by Rammelsberg according to the directions of Lamy a. Descloizeaux had, however, a different composition, and Rammelsberg therefore regards the salt in question as an isomorphous mixture of $(\text{NH}^+)\text{H}^+\text{PO}^+$ and Tl^+HPO^+ . He regards the hydrogen in phosphates as a so-called isomorphous constituent, and supposes that phosphoric acid itself is isomorphous with the phosphates $\text{H}^+\text{R}^+\text{PO}^+$, HR^+PO^+ , R^+PO^+ .

Tin and Titanium Phosphates.—Gustav Rose (*Berl. Akad. Monatsber.* Juli, 1867), by crystallising titanous acid from fused microcosmic salt, obtained flat plates which he regarded as anatase. W. Knop, however (*Ann. Ch. Pharm.* clvii. 363), found, by examination with polarised light, that they belonged to the rhombic, not to the quadratic system. They, moreover, had a specific gravity of only 2.0, whereas that of anatase is 3.890° – 3.927° . Further, on fusing them with potassium carbonate, dissolving in hydrochloric acid, and precipitating with ammonia, the filtrate was found to contain phosphoric acid, and quantitative analysis gave results from which Knop deduced the formula $3\text{TiO}^+\text{P}^-\text{O}^+$; he therefore inferred that the crystals consisted of phosphotitanic acid. *Stannic acid* crystallised in like manner from microcosmic salt, yielded pyramidal crystals consisting of, according to Knop's analysis, $2\text{SnO}^+\text{P}^-\text{O}^+$, and two kinds of cubic crystals, $\text{SnO}^+\text{P}^-\text{O}^+$ and $3\text{SnO}^+\text{P}^-\text{O}^+$, according to the proportions of the materials employed (*ibid.* elix. 36).

G. Wunder (*J. pr. Chem.* [2], iv. 330) finds, on the other hand, that all these compounds are double phosphates of tin or titanium and sodium.

Stannic oxide, fused with a mixture of borax and microcosmic salt, yields quadratic pyramids having the composition $\text{SnNa}^+\text{P}^-\text{O}^+$. Crystallised from microcosmic salt alone, it yields microscopic crystals which might be mistaken for cubes were it not for their action on polarised light; they have the composition $\text{Sn}^+\text{Na}^+\text{P}^-\text{O}^+$, and are sometimes accompanied by the quadratic prisms just mentioned. A goniometric examination of larger crystals of this species showed that they were not really cubes, but

rhombhedrons, the angles differing from a right angle by somewhat more than 2° . The formation of the quadratic prisms is facilitated when the stannic oxide is in relatively large quantity, or when borax is present. This is owing to the formation of trisodic phosphate, as was proved by direct experiment, the rhombhedrons being converted into the quadratic prisms, and *vice versa*, according as the flux contained less or more phosphoric acid :

Wunder attributes Knop's results to the fact of his having treated his crystals with fused phosphoric acid, whereby they were partly decomposed and the sodium removed.

The compound designated by Knop as phosphotitanic acid likewise contains sodium, and has a composition exactly analogous to that of the rhombhedronal tin salt, viz.: $\text{Ti}^2\text{Na}(\text{PO}_4)^2$. The crystals are rhombhedrons, differing but very slightly from cubes.

Attempts to prepare the compound $\text{TiNa}^2(\text{PO}_4)^2$, by adding basic sodium phosphate to the required flux, were unsuccessful (Wunder).

PETHALEINS and PHTHALINS. The name *phthalein* is applied by Baeyer (*Deut. Chem. Ges. Ber.*) to certain colouring matters produced by the combination of phthalic anhydride and phenols, monatomic or polyatomic, with elimination of one or more molecules of water. By the action of nascent hydrogen the phthaleins are converted into colourless compounds called phthalins, which, by oxidation in the air, are reconverted into phthaleins. Similar colouring matters are formed by the action of mellitic, pyromellitic, and oxalic acid on phenols in presence of sulphuric acid.

The phthaleins of resorcin, pyrogallol and naphthol have already been described : see FLUORESCIN (p. 524), GALLICIN (p. 534), NAPHTHOL (p. 830).

Phenol-phthalein, $\text{C}^{20}\text{H}^{14}\text{O}^4$.—When a mixture of 10 pts. phenol, 5 pts. phthalic anhydride, and 4 pts. strong sulphuric acid is heated to 120° – 130° for several hours, a red mass is obtained which, when treated with boiling water, yields a resin, and this resin is converted by boiling with water into a yellowish powder, which dissolves in potash, yielding a fuchsine-coloured solution, from which hydrochloric acid precipitates the phenol-phthalein in white resinous flocks. The formation of this body is represented by the equation :

Phenol-phthalein is isomeric with phenyl phthalate :

and these two isomeric compounds appear to be formed simultaneously by the action of phenol on phthalyl chloride.

The solution of phenol-phthalein in potash is decolorised by zinc-powder, and on adding sulphuric acid to the solution phenol-phthalein, $\text{C}^{20}\text{H}^{14}\text{O}^4$, is precipitated in white granules. This compound forms with potash a colourless solution, which turns red on exposure to the air.

PHTHALIC ACID, $\text{C}^8\text{H}^4\text{O}^4 = \text{C}^8\text{H}^4(\text{COOH})^2$. This acid is formed by oxidation of naphthaquinone with nitric acid (Liebermann and Dittler, *Deut. Chem. Ges. Ber.* i. 945).

Electrolysis.—The aqueous solution of phthalic acid conducts the current slowly, no oxygen being evolved at the positive pole. Potassium phthalate is easily decomposed, hydrogen being evolved at the negative pole, and the solution becoming alkaline, while at the positive pole phthalic acid is separated, only a small portion of it being oxidised to carbon monoxide and dioxide, which escape with the oxygen (Bourdin, *Ann. Chem. Phys.* [4], xxii. 361).

Bromophthalic acid, $\text{C}^8\text{H}^3\text{Br}(\text{COOH})^2$, is formed by heating phthalic acid with bromine (in the proportion 4 : 5) and water to 180° – 200° . A great part of the phthalic acid, however, remains unaltered, and may be separated by recrystallisation from water, the brominated acid remaining in the mother-liquor. The latter is converted into potassium salt, which is purified by repeated crystallisation from 90 p.c. alcohol, and the bromophthalic acid is separated by sulphuric acid and dissolved out by agitation with ether.

Pure bromophthalic acid is a white powder easily soluble in water, alcohol and ether. The *potassium salt*, $\text{C}^8\text{H}^3\text{BrO}^4\text{K}^2 + 2\text{H}^2\text{O}$, crystallises from hot alcohol in white shining deliquescent needles. The *barium salt*, $\text{C}^8\text{H}^3\text{BrO}^4\text{Ba} + 2\text{H}^2\text{O}$, is obtained from it by double decomposition. The *lead, copper, and silver salts*, obtained in like manner, are anhydrous. The *ethyl ether* is an oil having a faint yellow colour (A. Faust, *Ann. Ch. Pharm.* cl. 56).

2nd Sup.

3 B

Dichlorophthalic acid, $C^6H^2Cl^2(COOH)^2$, is obtained by boiling dichloronaphthalene tetrachloride, $C^{10}H^6Cl^2.Cl^4$, with ordinary nitric acid, and purified by repeated crystallisation from water. It dissolves easily in alcohol, ether, and hot water, and separates from the hot concentrated aqueous solution, sometimes not till after a day or two, in faintly yellowish prisms, often intergrown. It melts at 183° – 185° , and by repeated sublimation is wholly converted into dichlorophthalic anhydride, $C^6H^2Cl^2O^2$, which melts at 187° , and resembles benzoic acid in appearance.

Barium dichlorophthalate, $C^6H^2Cl^2O^4Ba$ + H^2O , separates on mixing an ammoniacal solution of the acid with barium chloride, in prisms which are sparingly soluble in water. The **calcium salt**, $C^6H^2Cl^2O^4Ca$ + $4H^2O$, prepared in like manner, forms yellowish prisms, sparingly soluble in water (Faust).

Nitrophthalic acid, $C^6H^3(NO^2)(COOH)^2$, is obtained by digesting phthalic acid for 24 hours with a mixture of equal parts of red nitric acid and sulphuric acid, and precipitating with water. It crystallises from ether in pale yellow prisms, which melt at 208° – 210° , being partly converted at the same time into the anhydride. It dissolves easily in water and in ether. By the action of tin and hydrochloric acid, it is converted into ordinary amidobenzoic acid, melting at 173° – 175° :

Neutral potassium nitrophthalate, $C^6H^3(NO^2)O^4K^2 + H^2O$, is precipitated from aqueous solution by alcohol in yellowish needles, permanent in the air, and easily soluble in water. From hot 90 p.c. alcohol it crystallises anhydrous. The **acid salt**, $C^6H^4(NO^2)O^4K + H^2O$, is precipitated on mixing a strong solution of the neutral salt with nitrophthalic acid, in white needles, less soluble in water than the neutral salt. The **ammonium salt**, $C^6H^4(NO^2)O^4(NH^4)^2$, is formed in large rhombic prisms on mixing a solution of the acid in strong ammonia with absolute alcohol, till a turbidity is produced. It dissolves easily in water, and crystallises therefrom with difficulty. The **acid ammonium salt**, $C^6H^5(NO^2)O^4(NH^4)$, separates on mixing the alcoholic solution of the neutral ammonium salt with nitrophthalic acid, in slender yellowish white needles, less soluble in water than the neutral salt. The **barium salt**, $C^6H^3(NO^2)O^4Ba + 2H^2O$, crystallises from its supersaturated aqueous solution in shining yellowish laminae, containing a variable amount of crystallisation-water. It is but slightly soluble in water. The **zinc salt**, $C^6H^4(NO^2)O^4Zn + \frac{3}{2}H^2O$, prepared by boiling an aqueous solution of the acid with zinc oxide, is a yellow crystalline powder. The **lead salt**, $C^6H^3(NO^2)O^4Pb + \frac{3}{2}H^2O$, is a white slightly soluble precipitate. The **silver salt**, $C^6H^3(NO^2)O^4Ag^2$, is a white, sparingly soluble powder.

The **neutral ethylic ether**, $C^6H^3(NO^2)O^4.(C^2H^5)^2$, is easily formed by passing gaseous hydrogen chloride into the warm solution of nitrophthalic acid in absolute alcohol. It is a faintly yellow, scentless oil, which boils with rapid decomposition, at a temperature above 300° (Faust).

The **acid ethylic ether**, $C^6H^4(NO^2)O^4.C^2H^5$, is formed on passing gaseous hydrogen chloride into the cold alcoholic solution of the acid, and remains on evaporating the alcohol, as an oil which gradually crystallises. By boiling its aqueous solution with barium carbonate, a barium salt is obtained which crystallises from water in stellate groups of easily soluble prisms.

Dinitrophthalic acid, $C^6H^4(NO^2)^2O^4$.—An acid having this composition is obtained by the action of a mixture of nitric acid and sulphuric acid on nitranisic acid. It is very sparingly soluble in cold water, and crystallises from boiling water in colourless rhombic tablets. The **ammonium salt** dissolves easily in water, and crystallises therefrom in stellate groups of thin yellow needles. The **barium salt**, $C^6H^2(NO^2)^2O^4Ba$, is also nearly insoluble in boiling water (Engelhardt u. Latschinoff, *Zeitschr. f. Chem.* [2], vii. 262).

Isophthalic Acid. V. Moyer (*Ann. Ch. Pharm.* clvi. 265; clix. 1) prepares this acid by the action of sodium formate on potassium sulphobenzoate:

The isophthalic acid thus prepared dissolves easily in alcohol and ether, is nearly insoluble in cold water, sparingly soluble in boiling water, and separates therefrom on cooling in flocks which melt above 300° . The **methylic ether** melts at 64° – 65° ; the **barium salt** contains 3 mols. water.

According to Storrs u. Fittig (*ibid.* cliii. 283) isophthalic acid (from xylene) dissolves in 460 pts. of boiling water, and in 7,800 pts. water at 25° . The **ethylic ether** $C^6H^4(COOC^2H^5)^2$, is a colourless liquid boiling at 285° , and solidifying at 0° to radio-crystalline mass.

Nitro-isophthalic acid, $C^6H^3(NO^2)(COOH)^2$, is prepared by boiling isophthalic

acid for three or four hours with fuming nitric acid, evaporating to dryness, and re-crystallising from water; or it may be purified by conversion into the calcium salt. It forms thin shining laminae which dissolve easily in water and in alcohol, and melt at 248° - 249° . Together with this acid there is formed a small quantity of another acid melting at 10° - 15° lower.

Calcium nitro-isophthalate, $C^6H^3(NO^2)O^2Ca$ + $3\frac{1}{2}H^2O$, is sparingly soluble in cold water, and turns reddish on exposure to light. The **barium salt**, $C^6H^3(NO^2)O^2Ba$ + $2\frac{1}{2}H^2O$, exhibits similar properties. The **ethyl ether** is unaffected by light, easily soluble in hot alcohol, sparingly soluble in cold alcohol, and in water. It melts at 83.5° .

Amido-isophthalic acid, $C^6H^4(NH^2)(COOH)^2$, crystallises from boiling water in laminae, from solutions containing acetic acid, and from alcohol, in prisms slightly soluble in cold water and in alcohol. It sublimes undecomposed when cautiously heated, but decomposes when rapidly heated. It forms very stable salts both with acids and with bases. The **hydrochloride**, $C^6H^4(NH^2)O^2.HCl$ + H^2O , is easily soluble in water, nearly insoluble in strong hydrochloric acid. The **sulphate**, $[C^6H^4(NH^2)O^2]^2.SO^2H^2$ + H^2O , dissolves easily in water, and crystallises therefrom in concentrically-grouped prisms. **Cupric amido-isophthalate** is formed as a green precipitate of variable composition, when the hydrochloride of amido-isophthalic acid is mixed with cupric acetate (Storrs u. Fittig).

Terephthalic Acid may be formed from solid dibromobenzene by treating the latter in ethereal solution with sodium and methyl iodide, distilling off the methylic ether and the resulting hydrocarbon after the action is finished, and oxidising the latter, after it has been purified by fractional distillation, with potassium chromate and sulphuric acid (V. Meyer, *Deut. Chem. Ges. Ber.* iii, 753).

PTHALIC CHLORIDE, $C^6H^2O^2Cl^2$, is readily obtained by boiling gently for several days a mixture of 1 mol. phthalic acid and 2 mols. phosphorus pentachloride to which a little oxychloride is added. As soon as the evolution of hydrochloric acid ceases, the product is distilled from an oil-bath, and the chloride boiling at 270° is collected separately. It is a yellowish oily liquid, which is heavier than water, and decomposed by it but slowly. When exposed to moist air, it is gradually converted in beautiful monoclinic crystals of phthalic anhydride, boiling at 275° (Ador).

PTHALYL, or **DIPHTHALYL**, $C^{10}H^4O^2 = (C^6H^4O^2)^2$, (Ador, *Ann. Ch. Pharm.* cxiv, 229): Phthalic chloride is very readily acted upon by silver dust; by gradually adding 14 pts. of the latter to 10 pts. of the chloride, a solid mass is obtained, which, in order to finish the reaction, may be heated for some time in an oil-bath to 150° . The products consist of phthalic anhydride, a portion of which sublimes during the latter operation, a resinous body soluble in alcohol, and diphtalyl, which is isolated by exhausting the product repeatedly with boiling water and with alcohol. The dried residue is then heated in a combustion-tube, through which a slow current of dry carbon dioxide passes, the diphtalyl subliming as a light, orange-coloured crystalline mass, which may be purified by dissolving it several times in hot phenol, and reprecipitating it by alcohol. The pure compound has a pale yellow colour; it is insoluble in water, scarcely soluble in alcohol and ether, sparingly soluble in chloroform, carbon sulphide, and liquid hydrocarbons. Phenol and cold concentrated sulphuric acid are the only liquids which dissolve larger quantities of it. It melts a little above 300° , subliming at the same time in soft felted needles. The formation of diphtalyl is explained by the equation:

When diphtalyl is heated in a current of air, a sublimate is obtained, consisting of phthalic anhydride, a red resinous body, and unaltered diphtalyl.

Diphtalylaldehydic Acid, $C^{10}H^4O^3$, is produced by dissolving diphtalyl in hot caustic alkalis; on the addition of hydrochloric acid to the solution, a bulky precipitate of the new acid is obtained. After drying it is a white, bulky, indistinctly crystalline powder; it is insoluble in water, very sparingly soluble in alcohol, ether, chloroform, petroleum-naphtha, and benzene, but dissolves readily in hot phenol, cold caustic soda, and solutions of alkaline carbonates.

When rapidly heated it melts only above 300° , but on heating it for six hours to 80° it becomes perfectly liquid, and then consists of a mixture of phthalic acid, a little diphtalyl, and an acid which has the composition $C^6H^4O^3$, and melts between 00° and 225° .

Neither the free acid nor any of its salts could be obtained in the pure state; the solutions of the latter soon deposit microscopic needles of diphthalyl; this decomposition takes place quickly on heating, and the yield is the larger the better the air has been excluded, whilst in contact with air much less diphthalyl is obtained. On adding hydrochloric acid to the remaining solution, a mixture of two acids is precipitated; one of them appears to be identical with the acid $C^{10}H^{10}O^3$; it is soluble in absolute alcohol and a large quantity of boiling water, from which it crystallises in prisms; the second acid, which is much less soluble in alcohol, is diphthalic acid, $C^{10}H^{10}O^4$; it is also formed by boiling the sodium salt of diphthalylaldehydic acid with silver nitrate, and by heating diphthalyl with concentrated nitric acid.

Diphthalic Acid forms microscopic needles or plates; it is almost insoluble in water, alcohol, and ether; sparingly in chloroform, carbon sulphide, and ether, but readily in solutions of the caustic alkalis and their carbonates and in phenol. It melts at 265° .

Barium diphthalate, $C^{10}H^8BaO^4 + 2H^2O$, crystallises in small colourless plates. **Silver diphthalate**, $C^{10}H^8Ag^2O^4$, crystallises from boiling water in small needles. A zinc salt of constant composition could not be obtained; the salts of the alkali-metals are very deliquescent, and form indistinct crystals; the *copper salt* is a bulky, bluish-white precipitate, and the *lead salt* a dense white precipitate. It is very difficult to obtain diphthalic acid and its salts perfectly pure, as they readily absorb oxygen. By boiling their alkaline solution, even in closed vessels, resinous acids and phthalic acid are formed, whilst when the operation is performed in open vessels only the latter acid is produced. Phthalic acid is also formed by heating diphthalic acid for some time with nitric acid, and, together with diphthalyl and phthalic anhydride, when diphthalic acid is heated a few degrees above its melting point.

The formation and constitution of diphthalylaldehydic acid and diphthalic acid, and the decomposition of the latter by heat, may be explained as follows:—

Dichlorodiphthalyl, $C^{10}H^4Cl^2O^4$, is produced by heating diphthalyl with phosphorus pentachloride and some oxychloride in sealed tubes for five hours to 160° . It crystallises from hot benzene in rhombic plates melting at 248° , and solidifying again at 196° . It is almost insoluble in alcohol, but readily soluble in alcoholic potash, with formation of potassium chloride, and a compound crystallising in hexagonal plates, probably a dioxydiphthalyl.

Diphthalyl dissolves in cold bromine, apparently without change, but on heating the mixture, hydrobromic acid is given off, and monobromodiphthalyl, $C^{10}H^3BrO^4$, is formed, together with a compound containing more bromine. Monobromodiphthalyl is easily obtained pure by heating diphthalyl with bromine and water in sealed tubes to 100° . It is soluble in benzene, and crystallises in small hexagonal plates.

The bye-products obtained in the preparation of diphthalyl always contain diphthalic acid; the formation of this acid may be explained by assuming that the phthalic dichloride used contained some phthalic monochloride, $C^6H^4 \begin{array}{c} \diagup \text{CO.OH} \\ \diagdown \text{COCl} \end{array}$.

In order to obtain this monochloride, phthalic anhydride was heated with somewhat less than 1 mol. of phosphorus pentachloride. The product consisted of unaltered phthalic anhydride, phthalic dichloride, and the compound $C^6H^3ClPO^3$, probably a combination of $C^6H^4 \begin{Bmatrix} COCl \\ COCl \end{Bmatrix}$ with $C^6H^3 \begin{Bmatrix} CO.OH \\ CO.Cl \end{Bmatrix}$. It crystallises in long plates, melting at 17° . On heating it with silver-dust, it yields, besides phthalic anhydride and diphtalyl, a considerable quantity of diphtallic acid.

The resinous bye-products contain, besides diphtallic acid, several other compounds; of these, one having the composition $C^{16}H^{10}O^1$ crystallises from boiling water in small white needles melting at 240° , with formation of phthalic anhydride. It is soluble in ammonia; silver nitrate produces in the neutral solution a white precipitate having the composition $C^{16}H^{10}Ag^2O^3$; the corresponding barium salt is obtained by dissolving the acid in baryta water, and evaporating the solution in a vacuum. It crystallises in small plates having the composition $C^{16}H^{10}BaO^3 + H^2O$. When the ammonium salt is boiled with silver nitrate, reduction takes place, and a compound having the properties of diphtallic acid is formed. The compound $C^{16}H^{10}O^1$ is therefore an anhydride, either $C^8H^4 \begin{Bmatrix} CO - CO \\ CH^2.O.CO \end{Bmatrix}$, C^8H^4 , or $C^8H^4 \begin{Bmatrix} CH^2 - CO \\ CO.O.CO \end{Bmatrix}$ C^8H^4 , which is probably formed by the action of diphtallic acid on diphtalyl:

PICOLINE, C^8H^7N . On the occurrence of this base and its homologues in tobacco-smoke, see *Tobacco*.

Picoline is formed by heating allyl tribromide with ammonia, dibromallylamino being formed in the first instance, and subsequently resolved into hydrobromic acid and picoline (Ador & Baeyer, *Jahresb. f. Chem.* 1870, 807):

and

The formation of picoline from acrolein-ammonia is noticed in the 1st *Suppl.* (p. 944). According to Claus (*Ann. Ch. Pharm.* clviii. 222), it is not a direct product of the 'decomposition' of acrolein-ammonia, but results from the secondary decomposition of a non-volatile base, which is formed in the first instance and partly distils over unaltered.

Oxidation-products.—Picoline is not acted on by nitric or chromic acid, even at high temperatures, but permanganic acid and the potassium salt act upon it with considerable energy. When 150 grams of potassium permanganate, 25 grams of picoline, and $1\frac{1}{2}$ litre of water were heated nearly to the boiling point in a flask with reversed condenser, a violent action took place, rendering it necessary to remove the source of heat; the reduction of the permanganate was completed in half an hour.

The products of this reaction are ammonia, probably a small quantity of pyridine, carbonic, nitric, acetic, oxalic, and a mixture of acids, amongst which dicarbo-pyridonic acid, $C^8H^3N \begin{Bmatrix} CO^2H \\ CO^2H \end{Bmatrix}$, predominates; this body, after several recrystallisations from water, was obtained in colourless plates resembling naphthalene. It is a bibasic acid; the neutral ammonium salt is extremely soluble in water; the acid salt is less soluble and crystallises in fine silky needles. The mercury, copper, cadmium, and zinc salts are also readily soluble. The barium and calcium salts, which are also soluble, were obtained in minute prismatic needles by adding the respective chlorides to a solution of the neutral sodium or ammonium salt. The silver salt is especially characteristic; it is obtained as a white gelatinous precipitate, insoluble in boiling water, and not visibly affected by exposure to light.

The oxidation of picoline likewise yields another acid of higher molecular weight, which still remains solid at 220° (Dewar, *Chem. News*, xxiii. 38).

Small quantities of picoline and its homologues have been found by Kramer & Pinner (*Deut. Chem. Ges. Ber.* iii. 75) in the 'first runnings' of spirit distillation.

PICRIC ACID. On the Thermic Relations of this compound, see *Heat* (p. 620).

Detection in Beer.—According to Sorby (*Qu. J. of Micros. Soc.* 1869, 358) picric acid may be very distinctly recognised in beer by means of its spectrum. The picric acid extracted by ether shows an absorption band at the blue end of the spectrum.

On the use of Picric Acid as a Precipitant for Alkaloids, see p. 43.

PICROTOXIN. According to J. Gaabe (*Russ. Zeitschr. Pharm.* x. 440, 461) picROTOXIN, treated with aqueous potash or baryta, yields compounds formed from it by addition of water and oxygen. The quantities of oxygen taken up varied in individual

experiments, and seemed to be greater the longer the mixtures of alkali and picrotoxin were heated in contact with the air. From the experiments of Barth (*1st. Suppl.* 643) and his own, Gaabe infers that picrotoxin is neither an acid nor a glucoside; and that it unites with bases only after having taken up water, or sometimes water and oxygen. Some of the experiments indicate the existence of acetyl-derivatives of picrotoxin and of its hydrates and oxygen-compounds.

PINACOLIC ALCOHOL, $C^8H^{14}O = (CH^3)_2COH-CH(CH^3)_2$, (Friedel a. Silva, *Compt. rend.* lxxvi. 226). This alcohol, isomeric with hexyl alcohol, is produced by treating pinacolin with sodium in presence of water, agitating the white substance thereby formed with water, and distilling the resulting liquid. Pinacolic alcohol then passes over as a liquid having a camphorous odour, boiling at 120.5° , and of sp. gr. 0.8347 at 0° . It solidifies at low temperatures to a mass of long silky needles melting at 4° . Treated with phosphorus iodide, or hydriodic acid, it yields the iodide, $C^8H^{13}I$, a liquid boiling at $140^\circ-144^\circ$, and having a sp. gr. of 1.4739 at 0° . Heated with water it partly decomposes, yielding a hexylene which boils at 70° . With silver acetate it yields pinacolic acetate, boiling at $140^\circ-143^\circ$, besides much hexylene. The chloride, obtained by the action of hydrochloric acid on the alcohol at 100° in closed tubes, boils at $112.5^\circ-114.5^\circ$, and has a density of 0.8891 at 0° .

By careful oxidation of the alcohol with potassium dichromate and sulphuric acid, pinacolin is reproduced. Pinacolin itself, when submitted to oxidation, yields a volatile crystalline acid melting at 20° .

The crystalline residue left in the retort after the removal of the pinacolic alcohol by distillation, melts at 69° , and is a pinacone of pinacolin:

The molecular complication does not stop at pinacolin, so that by starting from acetone it may be possible to obtain a series of these compounds by successive duplication.

PINACONE, $C^{12}H^{20}O^2$. When hydriodic acid gas is passed over pinacone contained in a retort connected with a reversed condenser, the gas is absorbed, with great evolution of heat and liberation of iodine. The saturation is completed by gently warming the liquid; the contents of the retort are distilled; the distillate washed with aqueous potash and water—no organic acid being thereby dissolved; and the product is dried with phosphoric anhydride and distilled. The liquid begins to boil at 40° , impure isopropyl iodide passes over at $88^\circ-96^\circ$, and there remains only a very small quantity of a residue boiling at a higher temperature. By heating the crude isopropyl iodide for 16 hours with ten times its volume of water, $\frac{1}{5}$ ths of it is dissolved, a heavy oil remaining undissolved. The aqueous solution contains isopropyl alcohol, which when separated and dried boils at $80^\circ-82^\circ$.

When the portion of the crude product of the action of hydriodic acid on pinacone which boiled below 88° was heated to 100° for sixteen hours with ten times its volume of water, a small quantity of a colourless very volatile hydrocarbon was obtained, which distilled between 50° and 72° (the greater part at 70°), and gave by analysis numbers agreeing with the formula of hexane, C^6H^{14} .

It appears, then, that pinacone is converted by hydriodic acid (as by dilute acids) into pinacolin, which is further resolved into isopropyl alcohol and hexane:

(Linnemann, *Wien. Akad. Ber.* [2 Abth.] lxiii. 255).

PINOLIN. A light oil obtained in the distillation of 'rosin-oil.'

PIPERONAL, $C^8H^8O^2$, and **PIPERONYLIC ACID**, $C^8H^8O^4$. These bodies, which stand to one another in the relation of aldehyde and acid, are formed by the oxidising action of potassium permanganate on piperic acid. They were first obtained by Fittig a. Mielek, who studied many of their properties and reactions, and the examination has been continued by Fittig a. Remsen. The principal results of these researches have been detailed in the First Supplement (pp. 947-949). The following are additional results obtained by Fittig a. Remsen (*Ann. Ch. Pharm.* clix. 129; *Chem. Soc. J.* [2], ix. 936).

Action of Baryta-water, Hydrochloric acid and Water, on Piperonylic acid.—A boiling aqueous solution of barium hydrate does not act on piperonylic acid. Dilute hydrochloric acid decomposes it at 170° into protocatechuic acid and free carbon:

Water acts in a similar manner, but the decomposition does not take place below 210° , at which temperature the protocatechuic acid is resolved into carbon dioxide and pyrocatechuic acid:

In like manner piperonal heated to 200° with very dilute hydrochloric acid (10 or 12 vols. water to 1 vol. of the concentrated acid) is resolved into carbon and protocatechuic aldehyde: $\text{C}^6\text{H}^4\text{O}^2 = \text{C} + \text{C}^6\text{H}^4\text{O}^2$.

Action of Phosphorus pentachloride on Piperonylic acid.—The action is similar to that which takes place with piperonal (1st Suppl. 948). When 1 mol. piperonylic acid is heated with 3 mols. PCl_5 , hydrochloric acid, phosphorus trichloride and oxychloride are formed, together with an oil which, when treated with water, yields dichloro-piperonylic acid, $\text{C}^6\text{H}^3\text{Cl}_2\text{O}^4$, and this when heated is completely resolved into hydrochloric acid, carbon dioxide, and protocatechuic acid:

affording a proof that the compound formed in like manner from dichloropiperonal is really protocatechuic aldehyde.

The experiments above mentioned, together with those described in the First Supplement, show that in piperonal the two oxygen-atoms not belonging to the aldehydic group, CHO, occupy a peculiar position, and that the formula previously assigned to this body must be rejected. The structural formulae of piperonal and piperonylic acid most in accordance with the reactions of these bodies are the following:

representing piperonal as the methylenic ether of protocatechuic aldehyde, and piperonylic acid as methylene-protocatechuic acid. When these bodies are subjected to the action of phosphorus pentachloride, the aldehyde-group, CHO, of the one, and the carboxyl of the other, are first attacked, yielding:

These bodies can lose no more oxygen by the action of pentachloride, and consequently any further action must result in the replacement of hydrogen by chlorine, producing:

which are exceptionally unstable bodies, the chlorine last introduced being analogous to that of carbonyl chloride, COCl^2 . These compounds, in presence of water, exchange their Cl^2 for O, producing:

which immediately split up on contact with water, yielding respectively protocatechuic aldehyde and protocatechuic acid.

Synthesis of Piperonylic acid.—That this acid really has the constitution of methylene-protocatechuic acid is proved by the fact that it may be formed synthetically by heating 1 mol. protocatechuic acid, 3 mols. potassium hydrate, and $1\frac{1}{2}$ mol. methylene iodide in a sealed tube for several hours, first at the heat of the water-bath, and finally to 140° in an air-bath. On treating the nearly black contents of the tube with alcohol, heating the extract thus obtained with potash for some time to decompose any methylene-ether of the methylene-protocatechuic acid that may have formed, then adding hydrochloric acid, filtering from the brown amorphous precipitate thereby produced, and evaporating the filtrate, crystals are obtained which, after recrystallisation, treat-

ment with animal charcoal, and sublimation, exhibit the melting point (227°) and all the other characters of piperonylic acid (Fittig a. Remsen, *Zeitschr. f. Chem.* [2], vii. 289).

In a precisely similar manner ethylene-protocatechuic acid, $C^6H^8 \begin{Bmatrix} O \\ \diagup \diagdown \\ O \end{Bmatrix} \begin{matrix} C^6H^4 \\ COOH \end{matrix}$,

may be prepared by heating protocatechuic acid with ethylene bromide and potassium hydrate (Fittig a. Macalpine, *ibid.* 291). See **PROTocatechuic Acid**.

PITTICITE. A specimen of this mineral from Rodruth in Cornwall, analysed by A. H. Church (*Chem. News*, xxiv. 99), exhibited the composition given under A; and, assuming that all the water driven off at 100° is hygroscopic, these numbers may be reduced by calculation to those under B:

	H ² O at 103°	H ² O at 175°	Loss by ignition	Fe ² O ³	As ² O ³	P ² O ⁵	SO ²
A.	8.76	7.53	8.63	32.54	33.99	1.27	7.28 = 100
B.	—	17.71		35.67	37.25	1.39	7.98 = 100

W. Gümbel (*Münch. Akad. Ber.* 1870, i. 195) has analysed an iron sinter resembling pitticite, imbedded, in lumps of the size of a man's head and having a pitchy lustre, in a crumbling brown hæmatite which fills up a cleft in the fresh-water limestone in the Spitzberg in the Ries. From its mode of occurrence Gümbel infers that it has been deposited from a spring, and he remarks that arsenic is found in many vitreous deposits from still active springs. The deposit contained phosphoric acid and 2.28 p.c. calcium carbonate. A complete analysis by Putz gave:

As ² O ³	Fe ² O ³	CaO	MgO	BaO	H ² O	X*	Y†
31.3	28.0	10.0	0.08	3.15	20.3	2.6	1.8 = 98.63

* Insoluble in hydrochloric acid, amounting in some specimens to 6 p.c., and consisting chiefly of ferruginous clay. † Loss and CO².

PLATINUM. *Fusibility.*—W. Skay (*Chem. News*, xxii. 268) observed that platinum in the form of fine wire may be fused in an ordinary blow-pipe flame if the loss of heat by conduction be prevented. E. J. Chapman (*ibid.* xxiii. 33) remarks that this fact has long been known, being mentioned in Plattner's 'Probirkunst,' p. 16, in Lenz's 'Lothrohrschule,' and Bruno-Kerl's 'Leitfaden.'

H. Violette (*Compt. rend.* lxxv. 1027) states that he has fused platinum in an ordinary furnace without the aid of a blast, and describes the furnace in which the fusion was effected. Dumas (*ibid.* 1028) suggests that the platinum may have contained traces of carbon, silicon, or sulphur, all which substances are known to lower its melting point considerably.

Action of Hydrogen sulphide and Alkalis.—Skay finds that platinum immersed in aqueous sulphydric acid or ammonium sulphide becomes covered, like gold (p. 573), with a layer of sulphide which protects it from the action of mercury; the film may, as also in the case of gold, be removed by chromic acid. Platinum, immersed in a solution of ammonia or a fused alkali, becomes coated with a film of oxide which likewise completely protects it from amalgamation.

Platinum-Black.—E. Smith (*American Chemist*, 1872, ii. 291) prepares platinum-black by reducing potassium platinochloride with hydrogen, dissolving out the potassium chloride with water, and drying the residue at a temperature not above 100° .

On the Separation of Platinum from Iridium, see **IRIDIUM** (p. 684).

On the Alloys of Platinum and Lead, see **LEAD** (p. 729).

Chlorides. According to Mather (*Sill. Am. J.* [2], xxxii. 262), *platinic chloride*, crystallised from aqueous solution, has the composition $PtCl^4 + 10H^2O$; according to a more recent analysis by Bödecker (*Jahresb. f. Chem.* 1872, p. 277) it contains $PtCl^4 + 8H^2O$. H. Lawson (*Zeitschr. f. Chem.* [2], vii. 615) states that, according to analyses by Prottopow, the chloride separated in large prismatic crystals from an aqueous solution evaporating in the exsiccator, has the composition $PtCl^4 + 10H^2O$. It is remarkable that those crystals, in spite of their large amount of water, deliquesce very quickly on exposure to the air.

A new hydrate of platinic chloride is described by S. A. Norton (*J. pr. Chem.* [2], ii. 469). When 1 mol. platinic chloride in aqueous solution is mixed with a solution of 2 mols. silver nitrate, the double chloride $AgCl.PtCl^4$, described by Commaillé (1st Suppl. 652), separates out. The filtrate, which is free from silver, gives off acid on evaporation, and if then left over sulphuric acid, deposits large well-defined red crystals which appear to be monoclinic, and contain nothing but chlorine and platinum in the proportion to form the tetrachloride together with water. This hydrated chloride

does not deliquesce in the air; when mixed with sal-ammoniac it gradually, after long standing or on heating, deposits ammonium platinochloride. It is not produced by evaporating a solution of platinic chloride containing excess of hydrochloric acid.

A compound of platinic chloride with *alcohol*, $\text{PtCl}^{\text{Cl}}_2 \cdot 2\text{C}^{\text{H}}_2\text{O}$, is obtained by evaporating a solution of the chloride in absolute alcohol in a dry vacuum. It then remains as a crystalline reddish-yellow mass, which is extremely deliquescent, and decomposes at 50° (Schützenberger, *Compt. rend.* lxx. 1134).

Platosochlorosulphites (Birnbaum, *Ann. Ch. Pharm.* clix. 116).—The formation of platosochlorosulphurous acid, $\text{Pt}^{\text{Cl}} \left\{ \text{SO}^{\text{H}}_2 \right\}$, by the action of sulphurous acid on ammonium platinochloride, is noticed in the 1st *Suppl.* (p. 1066), where also its ammonium and potassium salts are described. The *sodium salt*, $\text{Pt}^{\text{Cl}} \left\{ \text{SO}^{\text{Na}}_2 \right\} \cdot 2\text{NH}^{\text{Cl}}_4 + \text{H}^{\text{O}}_2$, obtained by neutralising the free acid with sodium carbonate, forms shining orange-coloured needles. The *calcium* and *magnesium salts*, prepared in like manner, are extremely deliquescent, so that they cannot be obtained in distinct crystals, but only as felted masses of fine needles. The magnesium salt especially has a beautiful satiny lustre. The analyses of these salts (disregarding accidental admixtures of NH^{Cl}_4 and H^{O}_2) led to the formulae:

On neutralising the acid with caustic baryta, barium sulphite is first formed, and afterwards small reddish-yellow crystalline leaflets having the composition:

By acting on ammonium platinochloride or platosochlorosulphurous acid with acid ammonium sulphate, both the chlorine-atoms of platinochloride may be replaced by the group SO^{H}_2 . In the former case beautiful colourless prisms are obtained which, when neutralised with potassium carbonate, yield a salt having the composition $\text{Pt}^{\text{Cl}} \left\{ \text{SO}^{\text{K}}_2 \right\} + \text{SO}^{\text{H}}_2 \left\{ \text{NH}^{\text{H}}_4 \right\} + 3\text{H}^{\text{O}}_2$; the original acid compound probably had the composition $\text{Pt}^{\text{Cl}} \left\{ \text{SO}^{\text{H}}_2 \right\} + \text{SO}^{\text{H}}_2 \left\{ \text{NH}^{\text{H}}_4 \right\} + 4\text{H}^{\text{O}}_2$, which indeed was confirmed by the platinum determination. The salt $\text{Pt}(\text{SO}^{\text{H}}_2)_2 \cdot 2\text{NH}^{\text{H}}_4\text{Cl} + \text{H}^{\text{O}}_2$, formerly described by Birnbaum (1st *Suppl.* 1066), he was not able to reproduce. By treating platosochlorosulphurous acid with acid ammonium sulphite, colourless prisms are obtained represented by the formula $\text{Pt}(\text{SO}^{\text{H}}_2)_2 \cdot 2\text{NH}^{\text{H}}_4\text{Cl}$, and agreeing very nearly in percentage composition with the salts formerly described. When sulphurous anhydride is passed for some time into an aqueous solution of ammonium platinochloride, and the liquid is neutralised with sodium carbonate, the salt, $\text{SO}^{\text{Na}}_2\text{Pt} \cdot 3\text{SO}^{\text{Na}}_2$, first described by Litton a. Schnederman (v. 540), is produced. Birnbaum regards this salt as $\text{Pt}(\text{SO}^{\text{Na}}_2)_3 \cdot 3\text{SO}^{\text{Na}}_2$.

Platinocarbonyl Chlorides (Schützenberger, *Ann. Chim. Phys.* [4], xxi. 350). Platinochloride unites with carbon monoxide, forming the following compounds:

When spongy platinum is heated to 240° – 250° in a glass tube about half an inch wide, placed in an oil-bath, and dry chlorine is passed over it till it is wholly converted into dichloride, that is to say as long as the chlorine continues to be absorbed,

and the stream of chlorine is then replaced by carbon monoxide or a mixture of that gas with the dioxide, the cold part of the tube becomes coated with a mixture of the second and third compounds above mentioned, and from this mixture the pure compounds may be prepared.

Platinocarbonyl Chloride, $\text{Cl}^1\text{Pt}^1\text{CO}$ (Schützenberger's *Carbonyl chloroplatinite*), is obtained by heating the crude product to 150° , the di- and tri-carbonyl compounds then giving off carbon monoxide. Heated to 240° in a stream of carbon dioxide, it sublimes in long golden-yellow needles which melt at 195° to a transparent orange-yellow liquid. It dissolves in hot carbon tetrachloride, and separates in needles on cooling. Water decomposes it into platinum, carbon monoxide, and hydrochloric acid, but the reaction is not definite, and part of the platinum remains in solution. With alcohol it yields ethylic chlorocarbonate. At 300° – 400° it is resolved into platinum and carbonyl chloride, part of it, however, subliming undecomposed. Heated in a stream of carbon oxide to 150° , it is converted into platino-dicarbonyl chloride, and at 250° the tricarbonyl compound is also formed in considerable quantity.

Platino-dicarbonyl Chloride, $\text{Cl}^1\text{Pt}^1\text{C}^2\text{O}^2$ (*Dicarbonyl chloroplatinite*), is obtained by heating the original crude product in a stream of carbon oxide to 150° . It sublimes slowly at that temperature in an atmosphere of the same gas, in white needles which melt at 142° to a yellow transparent liquid solidifying in long needles. It is decomposed by water into platinum, hydrochloric acid, carbon dioxide and carbon monoxide; gives off carbon monoxide at 210° , and is converted into platino-tricarbonyl tetrachloride; and when heated to 150° in a stream of chlorine, gives off carbonyl chloride, and yields a dark red liquid which solidifies at 120° to a red translucent amorphous mass containing 66.4 p.c. platinum and 22.4 chlorine.

Platino-tricarbonyl Tetrachloride, $\text{Cl}^1\text{Pt}^1\text{C}^3\text{O}^3$ (*Sesquicarbonyl chloroplatinite*).—This compound is obtained in the pure state when the crude product is treated with boiling carbon tetrachloride, and the first crystallisations are collected apart; it is much more soluble in that liquid than the dicarbonyl compound, and crystallises therefrom in slender yellow needles which melt at 130° , and are converted at 250° , with loss of carbon monoxide, into platinocarbonyl chloride, $\text{Cl}^1\text{Pt}^1\text{CO}$. Water and alcohol separate platinum from it, in the former case according to the equation:

Heated in an atmosphere of carbon monoxide, it is permanent, like the dicarbonyl compound, even at temperatures at which, in an indifferent gas, it would be converted into $\text{Cl}^1\text{Pt}^1\text{CO}$.

Platino-ethylene-carbonyl Chloride.—Ethylene-carbonyl chloroplatinite (*Chloroplatinite d'éthylène carbonyle*). When dry ethylene gas is passed over platino-monocarbonyl chloride heated to 95° , it is absorbed, and a yellow liquid is formed, probably having

the composition $\text{Cl}^1\text{Pt}^1 \begin{matrix} \text{CO} \\ \diagup \quad \diagdown \\ \text{C}^2\text{H}^4 \end{matrix}$. If the heat be raised a little above 0° , hydrochloric acid is formed, and at the end of the reaction there remains a dark-coloured product insoluble in water and not decomposed thereby. Its analysis led to the formula $\text{C}^2\text{H}^4\text{Cl}^1\text{Pt}^1\text{CO}$, whence it should be formed according to the equation:

Platinocarbonyl Diamines (Schützenberger, *loc. cit.*) The mono- and dicarbonyl chlorides above described are attacked by dry ammonia even at ordinary temperatures, but the alteration is incomplete and merely superficial; if, however, the temperature be raised to the melting point, a thorough decomposition takes place, attended with formation of sal-ammoniac and separation of platinum. If the reaction be moderated by passing dry ammonia-gas into a solution of platinocarbonyl chloride in carbon tetrachloride, the liquid becomes decolorised and deposits light yellow flocks consisting of platinocarbonyl-diamine hydrochloride, $(\text{NH}^4)^2\text{PtCO} \cdot 2\text{HCl}$. Platino-dicarbonyl chloride, treated in a similar manner, yields platino-dicarbonyl-diamine hydrochloride, $(\text{NH}^4)^2\text{PtC}^2\text{O}^2 \cdot 2\text{HCl}$.

Both these compounds melt when heated, and are resolved into platinum, sal-ammoniac, nitrogen, hydrogen, and a pungent-smelling liquid which, when treated with water, yields hydrochloric acid and a volatile acid which reduces silver salts, and is therefore probably formic acid. Schützenberger supposes that the volatile liquid is formyl chloride, $\text{CHO} \cdot \text{Cl}$. It is produced in a small quantity only, and often does not appear at all, being resolved into hydrochloric acid and carbon monoxide. Its formation may perhaps be represented by the equation:

Water decomposes the hydrochloride of platinocarbonyl diamine, according to the equation:

Phosphoplatinic Compounds (Schützenberger, *Bull. Soc. Chim.* [2], xiv. 178; xvii. 482; xviii. 101, 148). Baudrimont observed that platinum is attacked at about 200° by phosphorus pentachloride, forming a brown substance which he regarded as a compound of phosphoric chloride and platonic chloride, $2\text{PCl}_5 \cdot \text{PtCl}_4$ (iv. 512). Schützenberger, however, has shown that this body is really a compound of phosphorous chloride and platinous chloride, formed according to the equation:

This compound, analogous in constitution to platinocarbonyl chloride, $\text{PtCl}_2 \cdot \text{CO}$, is capable, like the latter, of taking up diatomic groups such as PCl_3 , CO , C_2H_4 , Cl_2 , &c., and forming compounds such as $\text{PtCl}_2 \cdot 2\text{PCl}_3$, $\text{PtCl}_2 \cdot \text{PCl}_3 \cdot \text{CO}$, &c.

Schützenberger designates the compounds $\text{PtCl}_2 \cdot \text{PCl}_3$ and $\text{PtCl}_2 \cdot 2\text{PCl}_3$ as *phosphoplatinous chloride* and *phosphoplatinic chloride*; but as the platinum in both of them is tetratomic, it is better to name them *phosphoplatinic* and *diphosphoplatinic chloride*.

These two chlorides easily exchange the chlorine which is united to the phosphorus for hydroxyl, the first yielding a tribasic and the second a sexbasic acid; but the two chlorine-atoms united with the platinum resist the action of water, and behave like the chlorine of metallic chlorides, being replaceable by acid radicles.

In accordance with these facts the composition of these chlorides may be represented by the following structural formulæ, in both of which the platinum is quadrivalent and the phosphorus quinquivalent:

When phosphoplatinic chloride takes up a bivalent group, the double linking between the phosphorus and platinum is severed, the bivalent group thus introduced satisfying the platinum by one of its atomicities and the phosphorus by the other, e.g. in the formation of diphosphoplatinic chloride by addition of PCl_3 .

Monophosphoplatinic Compounds.

Chloride, $\text{Cl}^2\text{Pt}=\text{PCl}^3$. This compound is formed by heating thoroughly dried spongy platinum and phosphorus pentachloride in molecular proportion to 250° in a long-necked flask, continuing the heat for half an hour after the first action is over, and then decanting the fused mass to separate a small quantity of uncombined platinum. On cooling, a red-brown crystalline mass is obtained made up of felted needles. If the liquid portion be decanted before the whole has solidified, the flask will be found lined with a druse of splendid large needles grouped in tufts. The compound may also be purified by crystallisation from chloroform or benzene.

Phosphoplatinic chloride crystallises in beautiful maroon-coloured needles which melt at 170° , and dissolve with aid of heat in carbon tetrachloride, chloroform, benzene, and toluene, the last two liquids dissolving it in considerable quantity. When cautiously heated it is gradually resolved into platinous chloride and phosphorous chloride; when quickly heated it gives off phosphoric chloride and leaves a residuum of platinum, a small portion also volatilising unaltered.

Phosphoplatinic chloride gently heated in a stream of chlorine, takes up 2 atoms of chlorine, and forms a yellow powder which has the composition $\text{Cl}^2\text{Pt}=\text{PCl}_4$, and is resolved at a heat below 200° into phosphorus trichloride and platinum tetrachloride.

Phosphoplatinic chloride dissolves rapidly in water, forming a solution which contains hydrochloric acid and tribasic phosphoplatinic acid:

the water removing only three-fifths of the chlorine. *Alcohols* act in the same manner, forming phosphoplatinic ethers; e.g.

Glycerin is likewise attacked by phosphoplatinic chloride, with evolution of hydro-

chloric acid and formation of a syrupy substance soluble in water. With *acetic acid*, the products are acetyl chloride and phosphoplatinic acid :

Ammonia and alcoholic amines unite directly with phosphoplatinic chloride, forming complex bases which will be described further on.

Phosphoplatinic chloride unites directly with phosphorus trichloride, forming di-phosphoplatinic chloride, $\text{Cl}^2\text{Pt}=\text{P}^2\text{Cl}^3$.

Phosphoplatinic Acid, $\text{Cl}^2\text{Pt}=\text{P}(\text{OH})^3$. This tribasic acid is obtained by dissolving phosphoplatinic chloride in water, and evaporating the solution in a vacuum. It forms orange-red prismatic crystals, very deliquescent, and having a taste both acid and metallic. *Silver nitrate* produces in its solution a yellowish-white precipitate, not of constant composition, but probably containing $\text{Cl}^2\text{Pt}=\text{P}(\text{OH})(\text{OAg})^2$. With *neutral lead acetate* it gives a light yellow precipitate which, when washed with water and dried in a vacuum, contains $(\text{Cl}^2\text{Pt}=\text{PO}^3)^2\text{Pb}^3 + 8\text{H}^2\text{O}$; it is decomposed by heat, giving off a considerable quantity of water. *Basic lead acetate* forms a yellow precipitate which has the composition $(\text{Cl}^2\text{Pt}=\text{PO}^3)^2\text{Pb}^3.2\text{PbO} + 4\text{H}^2\text{O}$, and detonates slightly when heated.

The *alkali salts* of phosphoplatinic acid have not been prepared; on saturating the acid with an alkali or alkali carbonate, the liquid quickly blackens, and on addition of alcohol yields a precipitate not containing chlorine.

PHOSPHOPLATINIC ETHERS. The *acid allyl ether*, $\text{Cl}^2\text{Pt}=\text{P}(\text{OII})^2(\text{OC}^2\text{H}^3)$, is formed by the action of allyl alcohol on the chloride; it is crystallisable and soluble in water.

Amyl Phosphoplatinate.—When 3 mols. amyl alcohol are added to a solution of 1 mol. phosphoplatinic chloride in benzene, and the product is washed with water and evaporated at a gentle heat, a thick highly coloured residue is left which does not crystallise. A similar product is obtained by treating the chloride directly with amyl alcohol. The viscid substance treated with ammonia yields a glutinous, yellow-brown insoluble mass, and a colourless solution which, on evaporation, leaves a hydrochloride crystallising in white nacrous leaflets; this salt is analogous to a diamylic ether, and contains $(\text{C}^5\text{H}^{11}\text{O})^2(\text{OH})\text{P}=\text{Pt.N}^3\text{H}^4\text{Cl}$.

Ethyl Phosphoplatinate, $\text{Cl}^2\text{Pt}=\text{P}(\text{OC}^2\text{H}^3)^3$.—Phosphoplatinic chloride dissolves in absolute alcohol, with rise of temperature and elimination of hydrochloric acid. On diluting with water and exactly neutralising the solution with sodium carbonate, a yellow crystalline mass separates which is easily purified by crystallisation from alcohol. It is better, however, to leave the alcoholic solution of the chloride to evaporate in a vacuum, wash the crystallised residuum with water, and purify it by slow crystallisation from alcohol.

Ethyl phosphoplatinate forms large yellow triclinic prisms, insoluble in pure water, but soluble in water acidulated with hydrochloric acid, also in alcohol and in benzene. It melts at 83° , and decomposes at about 180° , giving off ethyl chloride, ethylene, hydrochloric acid, and, towards the end, marsh-gas and carbon monoxide, and leaving a grey residuum containing platinum and metaphosphoric acid. Ethyl phosphoplatinate, treated in alcoholic solution with *silver nitrate*, exchanges part, or the whole, of its chlorine for the nitric residuum NO^3 , forming red syrupy uncrystallisable compounds represented by the formulæ:

The alcoholic solution of ethyl phosphoplatinate immediately turns brown on addition of alcoholic potash-solution, depositing potassium chloride; and water added to the liquid throws down brown flocks which, in the dry state, take fire spontaneously in contact with the air; on redissolving these flocks in alcohol and evaporating the solution in a vacuum, a black amorphous mass is left possessing much greater stability. The analysis of this compound agrees approximately with the formula $\text{PtPO}(\text{C}^2\text{H}^3\text{O})^2$.

The alcoholic solution of ethyl phosphoplatinate, treated with *zinc* at common temperatures, turns brown, and yields, after some hours, on addition of water, a brown flocculent precipitate approximating in composition to the formula $[\text{PtP}(\text{OC}^2\text{H}^3)^3]^2\text{Zn}$. If the action of the zinc takes place at higher temperatures, an analogous compound is obtained having a darker colour, free from zinc, and agreeing approximately with the formula $\text{PtP}^2(\text{OC}^2\text{H}^3)^3$.

Ethyl phosphoplatinate unites directly with *phosphorus trichloride*, the combination being attended with evolution of heat, and resulting in the formation of ethyl di-phosphoplatinate, $\text{Cl}^2\text{Pt}=\text{P}^2\text{Cl}^3(\text{OC}^2\text{H}^3)^3$.

An alcoholic solution of ethyl chloroplatinate saturated with *ethylene* yields, after

evaporation of the alcohol, a light yellow oily liquid insoluble in alcohol, and having the composition :

This additive compound gives off its ethylene in contact with phosphorous chloride or ammonia.

Ethyl phosphoplatinate likewise unites directly with carbon monoxide when this gas is passed into its solution in anhydrous ether, yielding a light yellow oily compound

having the composition $\text{Cl}^2\text{Pt} \begin{array}{c} \text{P}(\text{OC}^2\text{H}^5)^3 \\ | \\ \text{CO} \end{array}$. This compound is soluble in alcohol,

ether, and benzene, but insoluble in water, and decomposes gradually in contact with water, yielding carbonic and hydrochloric acids, together with a yellow viscous body, $\text{ClPt}-\text{PH}(\text{OC}^2\text{H}^5)^3$, formed according to the equation :

Action of Ammonia on Ethyl Phosphoplatinate.—This ether combines directly with ammonia, forming bases of complex constitution. Its solution in ammonia yields, by evaporation, colourless deliquescent prismatic crystals of a salt very soluble in water and in alcohol. The same salt is more easily obtained by passing ammonia gas into a solution of ethyl phosphoplatinate in benzene, the liquid after a while solidifying to a mass of white crystals. This salt is the hydrochloride of a diamine, containing:

The *platinohydrochloride* of the same base is a light yellow precipitate which dissolves in hot water and crystallises on cooling in yellow prisms having the composition $(\text{C}^2\text{H}^5\text{O})^3\text{P}=\text{Pt}(\text{NH}^2.\text{HCl})^2.\text{PtCl}^4$.

When a solution of ethyl phosphoplatinate in absolute alcohol is saturated with ammonia gas, the liquid becomes colourless, and gradually deposits colourless crystals less deliquescent than the former. The compound thus formed is a complex double salt represented by the formula :

the first term of which is the hydrochloride above described.

This double hydrochloride, treated with strong aqueous potash, gives off ethylamine, and yields an oily product which, under the influence of very strong potash, is transformed by simple dehydration into a crystalline mass. This product is soluble in pure water and in alcohol, but very slightly soluble in potash-ley. Its solution evaporated over the water-bath leaves an amorphous colourless transparent residue, having the composition :

This substance is probably a mixture of two bases differing from the original alkaloids by containing a molecule less of ethylamine.

The double hydrochloride above mentioned melts at 150° , and decomposes, giving off ammonia and ethyl chloride, and leaving a brittle, vitreous, colourless, transparent mass, very soluble in water and in alcohol. This body, which has the composition $(\text{C}^2\text{H}^5\text{O})^3\text{P}=\text{PtON}^2\text{H}^2\text{Cl}$, may be regarded as the monohydrochloride of a diamine, or as the hydrochloride of an ammoniated monamine, viz. :

The chloroplatinate is a yellow precipitate containing 48.5 p.c. platinum, which agrees with the preceding formulæ.

On attempting to crystallise this body from boiling water, or on adding chlorine or a large excess of platinic chloride to the solution of the vitreous salt, a crystalline,

slightly yellowish deposit is obtained, which dissolves in boiling water, and crystallises therefrom in light yellow needles. This compound, which contains neither carbon nor phosphorus, is represented by the formula :

Ethyl phosphoplatinate combines also with solid *toluidine*. When an alcoholic solution of the ether is heated with an excess of this base, the liquid becomes decolorised, and yields on cooling a crystalline deposit which, when washed with dilute hydrochloric acid and repeatedly crystallised from boiling alcohol, yields colourless prismatic needles easily soluble in alcohol, very slightly soluble in water and in ether, and having the composition $(\text{C}^2\text{H}_5\text{O})^2\text{P}(\text{C}^2\text{H}_5\text{N})\text{PtCl}^2$. This compound, treated in alcoholic solution with potash, yields potassium chloride and a colourless product which crystallises in fine silky needles insoluble in water, and less soluble in alcohol than the preceding. Dried at 100° it has the composition $(\text{C}^2\text{H}_5\text{O})^2\text{P}(\text{C}^2\text{H}_5\text{N})\text{Pt}(\text{OH})^2$.

Methyl Phosphoplatinate, $\text{Cl}^2\text{Pt}=\text{P}(\text{OCH}^3)^2$.—Phosphoplatinic chloride acts strongly on methyl alcohol; and the resulting liquid evaporated in a vacuum yields a crystalline mass which may be purified by repeated crystallisation from alcohol, or by solution in benzene. The methylic ether separates by slow evaporation in slender orange-yellow needles, slightly soluble in pure water, soluble in water containing hydrochloric acid, also in alcohol, ether, and benzene; it melts and decomposes when heated.

Diphosphoplatinic Compounds.

Chloride, $\text{Cl}^2\text{Pt} \begin{matrix} \nearrow \text{PCl}^3 \\ \searrow \text{PCl}^3 \end{matrix}$.—This compound is easily prepared by dissolving phosphoplatinic chloride, with aid of heat, in excess of phosphorus trichloride. The solution on cooling deposits crystals which may be washed with a small quantity of benzene or chloroform, and desiccated at 100° in dry air. Or phosphorus trichloride may be added in equivalent proportion to a solution of phosphoplatinic chloride in benzene, the diphosphoplatinic chloride then crystallising out on cooling. Lastly it is formed, with evolution of carbon monoxide, by the action of phosphorus trichloride on either of the platinumcarbonyl chlorides, $\text{Cl}^2\text{Pt}=\text{CO}$ or $\text{Cl}^2\text{Pt}=\text{C}^2\text{O}^2$ (p. 985).

Diphosphoplatinic chloride forms beautiful canary-yellow crystals arranged in funnel-shaped groups with rectangular section. It melts at 160° , and decomposes at a higher temperature, giving off phosphorus trichloride. It dissolves in phosphorus trichloride, carbon tetrachloride, chloroform, benzene, and toluene. Water attacks it strongly, eliminating hydrochloric acid and forming diphosphoplatinic acid :

If the temperature rises during the reaction, another acid is obtained having the composition $\text{ClPtP}^2\text{O}(\text{OH})^5$, and derived from the former by loss of a molecule of hydrogen chloride (*infra*).

Ethylic alcohol and *methylic alcohol* dissolve the chloride, forming the corresponding ethers, e.g. :

Amylic alcohol reacts in a similar manner. With *glycerin*, hydrogen chloride is evolved, and a thick, nearly colourless mass is formed.

Diphosphoplatinic Acid, $\text{Cl}^2\text{Pt}=\text{P}^2(\text{OH})^6$, or, $\text{Cl}^2\text{Pt} \begin{matrix} \nearrow \text{P}(\text{OH})^3 \\ \searrow \text{P}(\text{OH})^3 \end{matrix}$. The preparation of this compound succeeds only at a low winter temperature. Diphosphoplatinic chloride is exposed to moist air, and as soon as it has deliquesced, the light yellow syrupy liquid is evaporated, also at a low temperature. The diphosphoplatinic acid is thus obtained in light yellow extremely deliquescent needles.

If during this operation the temperature rises to 10° or 12° , a colourless crystallisable acid is obtained, less deliquescent than diphosphoplatinic acid, differing from it by containing 1 mol. less of hydrogen chloride, and represented by the formula :

This acid is much more stable than diphosphoplatinic acid. When heated to 150° ,

it gives off water and is converted into a light yellow non-deliquescent powder, soluble in water, and having the composition:

The solution of the acid, $\text{ClPtOP}^2(\text{OH})^2$, gives, with silver nitrate, a white, slightly yellowish precipitate containing 6.83 P, 2.19 Cl, 23.33 Pt, and 51.25 Ag, numbers agreeing nearly with the formula $\text{ClPtOP}^2(\text{OH})(\text{OAg})^2$, supposing half the chlorine to be replaced by the residue NO^2 . The precipitate in question is probably a mixture of two salts.

The acid dehydrated at 150° forms with silver nitrate an analogous precipitate containing 5.5 Cl and 41.8 Ag, numbers which agree with the composition of a mixture in equivalent proportions of the *di-* and *tri-argentic* salts:

Ethyl Diphosphoplatinate. $\text{Cl}^2\text{Pt} = \text{Pt}^2(\text{OC}^2\text{H}^5)^2$, is easily formed by the action of absolute alcohol on diphosphoplatinic chloride. Water added to the resulting solution separates a light yellow oil which, when cooled to a low temperature, solidifies to a mass of prismatic crystals (mono- or tri-clinic). This ether sometimes remains for a long time in a state of supersaturation. When decomposed by heat it yields ethylene, ethyl chloride, platinum and phosphoric acid.

Ethyl diphosphoplatinate dissolves in aqueous ammonia, and the solution, evaporated in a vacuum, leaves a white crystalline mass, deliquescent and soluble in alcohol. The body thus formed is the hydrochloride of a monamine:

derived, not from ethylic diphosphoplatinate, but from a compound containing 1 mol. less of ethyl chloride.

Platinum Iodides. Topsoë (*Chem. Centr.* 1870, 683) confirms the observation made by Clementi (*Cimento*, ii. 192) that the platonic iodide prepared by precipitating platonic chloride with potassium iodide (iv. 671) contains excess of platinum, and adds that it is obtained in greater purity by the action of hydriodic acid on platonic chloride at ordinary temperatures. It gives off iodine at 130° . It dissolves in hydriodic acid and in solutions of metallic iodides, forming dark crimson solutions. Many of the double iodides are, however, more readily obtained by mixing solutions of metallic iodides with platonic chloride, and leaving them to crystallise. They have a brown colour, and metallic lustre, and their solutions deposit platonic iodide on standing, and more quickly on boiling. Sulphurous acid and alkaline sulphites decolorise their solutions, forming platinous sulphite.

Hydroplatonic Iodide, $\text{PtI}^4.2\text{HI} + 9\text{H}^2\text{O}$, forms large monoclinic deliquescent crystals. **Potassio- and Ammonio-platonic iodides** are anhydrous, and crystallise in the monoclinic system. **Sodio-platonic iodide**, $\text{PtI}^4.2\text{NaI} + 6\text{H}^2\text{O}$, is monoclinic. The **calcium salt**, $\text{PtI}^4.\text{CaI}^2 + 12\text{H}^2\text{O}$, crystallises in rhombohedrons of $106^\circ 31'$ in combination with an acute rhombohedron. The compounds of platonic iodide with the iodides of **magnesium, manganese, zinc, iron, cobalt, and nickel**, are represented by the general formula $\text{PtI}^4.\text{RI}^2 + 9\text{H}^2\text{O}$, and crystallise in hexagonal prisms combined with a rhombohedron of $76^\circ 17'$ to $76^\circ 27'$. At a higher temperature a **nickel salt**, $\text{PtI}^4.\text{NiI}^2 + 6\text{H}^2\text{O}$, crystallises in hexagonal prisms with a rhombohedron of $127^\circ 40'$.

Platonic Oxide. Topsoë finds that the hydrated platonic oxide prepared by Dübrenin's method, of evaporating a solution of platonic chloride with excess of sodium carbonate, and treating the residual mass suspended in water with acetic acid, is identical with that which Wittstein obtained by precipitating platonic nitrate with calcium carbonate (iv. 671), and has the composition $\text{PtO}^2 + 2\text{H}^2\text{O}$. Frémy's **platonic acid** (*Ann. Chim. Phys.* [3], xxxi. 478), prepared by boiling platonic chloride with a very large excess of sodium carbonate, and decomposing the resulting sodium platinate with acetic acid, and easily soluble in dilute acids, even in acetic acid, has, when dried over calcium chloride, the composition $\text{PtO}^2 + 4\text{H}^2\text{O}$, and gives off 2 mols. H^2O at 100° .

Platinates of Barium and Calcium.—By boiling a solution of platonic chloride with a quantity of baryta-water sufficient to render the liquid alkaline after boiling, Topsoë (*Zeitschr. f. Chem.* 1870, 682) obtained from dilute solutions yellowish-white scales having a silky lustre, and from concentrated solutions a dense straw-yellow precipi-

tate made up of feathery and stellate groups of microscopic crystals. This precipitate is extremely difficult of solution in water, baryta, and soda, easily soluble in dilute acids, with the exception of cold acetic acid; hot acetic acid separates platonic oxide from it. According to Topsoë's analysis this compound consists of barium platinate, $\text{BaPtO}_3 + 4\text{H}_2\text{O}$, and gives off 3 mols. (about 10 p.c.) water at about 300° . When an insufficient quantity of baryta is used, so that the liquid, after boiling, has a neutral or acid reaction, precipitates are obtained which must be regarded as mixtures or loose combinations of platonic acid with barium platinate (Topsoë). According to Johannsen, on the other hand (*Ann. Chem. Pharm.* clv. 204), the precipitates obtained by boiling platonic chloride with baryta-water all contain chlorine, the yellow precipitate formed when the baryta is in excess containing, according to eight analyses, 42.71-43.68 p.c. Pt, 4.75-6.44 Cl, 33.18-34.26 BaO, and 10.92-11.58 H_2O ; with excess of platonic chloride the precipitate is richer in platinum and chlorine, poorer in water and baryta. Johannsen also finds that a solution of platonic chloride mixed with excess of baryta-water, and exposed to sunshine, immediately deposits a pure yellow precipitate which, in diffused light, forms more slowly and separates in hard warty crystals; analysis gave the atomic relation $4\text{Pt} : 4\text{Ba} : 4\text{Cl} : 10\text{O} : 11\text{H}_2\text{O}$. With excess of platonic chloride there is formed a darker-coloured salt exhibiting the atomic relation $5\text{Pt} : 5\text{Ba} : 6\text{Cl} : 12\text{O} : 13\text{H}_2\text{O}$.

To prepare Herschel's 'sun-salt' (iv. 672), Johannsen used an excess of lime-water more than sufficient to precipitate all the platinum, and obtained a nearly white salt of constant composition, answering to the atomic relation, $2\text{Pt} : 2\text{Ca} : 2\text{Cl} : 5\text{O} : 7\text{H}_2\text{O}$. On heating platonic chloride with lime-water, precipitates are formed richer in platinum and chlorine, and poorer in lime and water in proportion as the excess of platonic chloride used is greater. Whether the chlorine in these compounds is directly associated with the platinum or with the barium or calcium has not yet been determined (Johannsen, *loc. cit.*)

PLATINUM-COMPOUNDS, AMMONIACAL. A large number of new compounds belonging to this class have been prepared by Cleve (*Bull. Soc. Chim.* [2], vii. 12; xv. 161; xvi. 203; xvii. 289; *Deut. Chem. Ges. Ber.* iv. 70, 673; vi. 1469; *Svenska Vetenskaps Akademiens Handlingar*, 1872, x. No. 9), and a new theory of their constitution, founded in great part on Cleve's researches, has been proposed by Blomstrand (*Deut. Chem. Ges. Ber.* iv. 40; *Chem. Soc. J.* [2], ix. 189).

The platinum in some of these compounds is bivalent (*plato* or *platoso*), and exchanges two of its combining units with the bivalent groups NH_2 or N^2H_4 , each of which retains one combining unit free. In others the platinum is quadrivalent (*platino*), and exchanges some of its combining units with ammonia or diammonia, the remaining units being satisfied by combination with electro-negative radicles. In others, again, the platinum accumulates in such a manner as to form compounds containing $(\text{Pt}^2)^2$, $(\text{Pt}^2-\text{Pt}^2)^2$, $(\text{Pt}^2-\text{Pt}^2-\text{Pt}^2-\text{Pt}^2)^2$, &c. The bivalent groups NH_2 , N^2H_4 , always go by pairs, excepting in the semi-diammoniums, in which half or a quarter of the combining units of the platinum is satisfied by once N^2H_4 .

The names and constitution of the several groups are given in the following table, the unsaturated combining units being denoted by dashes:

1. Platosammonium (Reiset's second base)	$\text{Pt}^2 \begin{Bmatrix} \text{NH}^2- \\ \text{NH}^2- \end{Bmatrix}$
2. Platosemidiammonium	$\text{Pt}^2 \begin{Bmatrix} \text{NH}^2(\text{NH}^2)- \\ - \end{Bmatrix}$
3. Platosomonodiammonium	$\text{Pt}^2 \begin{Bmatrix} \text{NH}^2(\text{NH}^2)- \\ \text{NH}^2- \end{Bmatrix}$
4. Platosodiammonium (Reiset's first base)	$\text{Pt}^2 \begin{Bmatrix} \text{NH}^2(\text{NH}^2)- \\ \text{NH}^2(\text{NH}^2)- \end{Bmatrix}$
5. Platinammonium (Gerhardt's base)	$=\text{Pt}^4 \begin{Bmatrix} \text{NH}^2- \\ \text{NH}^2- \end{Bmatrix}$
6. Platinosemidiammonium	$=\text{Pt}^4 \begin{Bmatrix} \text{NH}^2(\text{NH}^2)- \\ - \end{Bmatrix}$
7. Platinomonodiammonium	$=\text{Pt}^4 \begin{Bmatrix} \text{NH}^2(\text{NH}^2)- \\ \text{NH}^2- \end{Bmatrix}$
8. Platinodiammonium (radicle of Gros' and Raewsky's bases)	$=\text{Pt}^4 \begin{Bmatrix} \text{NH}^2(\text{NH}^2)- \\ \text{NH}^2(\text{NH}^2)- \end{Bmatrix}$
9. Diplatinammonium	$=(\text{Pt}^2)^2 \begin{Bmatrix} \text{NH}^2- \\ \text{NH}^2- \\ \text{NH}^2- \\ \text{NH}^2- \end{Bmatrix}$

10. Diplatoso-diammonium $(Pt^2)^+ \begin{Bmatrix} NH^2(NH^4) \\ NH^2(NH^4) \end{Bmatrix}$
 11. Diplatinodiammonium $\equiv (Pt^2)^+ \begin{Bmatrix} NH^2(NH^4) \\ NH^2(NH^4) \end{Bmatrix}$
 12. Diplatinotetradiammonium $\equiv (Pt^2)^+ \begin{Bmatrix} NH^2(NH^4) \\ NH^2(NH^4) \\ NH^2(NH^4) \\ NH^2(NH^4) \end{Bmatrix}$

The following is an enumeration of all the ammoniacal platinum-compounds at present known. Some have been already described (iv. 673-678, and 1st Suppl. 952-955); and of these only the names and formulæ are here given. The rest, nearly all of which have been discovered by Cleve, will be shortly described.

1. **Platosammonium Compounds**, $Pt^+ \begin{Bmatrix} NH^2R \\ NH^2R \end{Bmatrix}$ (R in this and all the following formulæ denoting an electro-negative univalent radicle).

Bromide, $PtN^2H^4Br^2$.—Crystalline, very slightly soluble precipitate obtained by double decomposition with the nitrate.

Platocyanide, $PtN^2H^4(CN)^2.Pt^+$.—Orange-coloured, amorphous precipitate.

Sulphocyanate, $PtN^2H^4(CNS)^2$.—Thin yellow crystals. Its solution gives with silver nitrate a yellow precipitate containing $PtN^2H^4Ag^4(CNS)^6$. Yellow crystals, isomeric with those just mentioned, are obtained on adding ammonia to a solution of potassium platosulphocyanate.

Nitrite, $Pt^+N^2H^4(NO^2)^2$.—Obtained by double decomposition. It is a white crystalline powder, very slightly soluble in cold water, easily soluble in boiling water. Decomposes violently when heated. Nitric acid converts it into nitroso-nitrate of platinumammonium, $(NO^2)^2Pt^+(N^2H^4)(NO^2)^2$. It unites with chlorine and bromine, forming the bromo- and chloro-nitrites of platinumammonium, e.g. $Cl^2Pt^+(N^2H^4)(NO^2)^2$.

Sulphite, $PtN^2H^4CO^2$.—Obtained by passing sulphur dioxide into a boiling solution of the nitrite. The solution, which at first turns green, is filtered as soon as it becomes colourless, and evaporated over the water-bath, and the residue, after washing with alcohol, is redissolved in water. The solution yields by spontaneous evaporation delicate colourless crystals.

Chlorosulphite, $PtN^2H^4(SO^2H)Cl$.—Obtained in needles by treating a boiling solution of platosammonium chloride with sulphurous acid, and leaving it to evaporate. Peyrone, by treating the chloride with ammonium sulphite, obtained a compound probably containing $PtN^2H^4(SO^2NH^4)Cl$.

Double Sulphites.—These salts are analogous to the unknown acid sulphite, $PtN^2H^4(SO^2H)^2$. Peyrone obtained the ammonium salt by treating the chloride with

ammonium sulphite in excess. It forms colourless, well-defined crystals. The following salts are obtained from it by double decomposition (Cleve):—

Silver salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Ag} + \text{H}_2\text{O}$	White crystalline powder
Barium salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Ba}$	Crystalline powder
Manganous salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Mn}$	Dense crystalline precipitate
Zinc salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Zn} + 6\text{H}_2\text{O}$	Flattened microscopic prisms
Nickel salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Ni} + 7\text{H}_2\text{O}$	Bluish crystalline powder, which does not give off its water at 100°
Cobalt salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Co} + 6\text{H}_2\text{O}$	Small rose-coloured crystals
Cupric salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2\text{Cu} + 5\text{H}_2\text{O}$	Bluish-green flattened prisms
Uranyl salt,	$\text{PtN}^{\text{H}}\text{H}^{\text{H}}(\text{SO}_3)_2(\text{UO}_2)^{\text{H}} + 2\text{H}_2\text{O}$	Yellow crystalline powder, giving off $1\text{H}_2\text{O}$ at 100°
Lead salt		Amorphous precipitate

2. **Platosemidiammonium Compounds**, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}}\text{R} \\ \text{R} \end{smallmatrix}\right.$. These compounds, isomeric with the platossammonium compounds, are formed by addition of ammonia to a platinum salt, whereas the platossammonium salts are formed by abstraction of ammonia from the platossodiammonium (tetrammonio-platinum) compounds (iv. 673).

Chloride, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}}\text{Cl} \\ \text{Cl} \end{smallmatrix}\right.$. This is the yellow salt, isomeric with platossammonium chloride (Reisot's salt), and with the green salt of Magnus (iv. 674), which Peyron obtained by adding ammonia to a cold solution of platinum chloride in hydrochloric acid, filtering after 24 hours, and treating the yellowish-green residue with boiling water, which dissolves the yellow and leaves the green salt formed at the same time. The solution on cooling deposits the platosemidiammonium salt in small yellow prisms, which appear to differ in form from platossammonium chloride. They are more soluble, requiring only 387 pts. of cold and 26 pts. of boiling water. This salt is decomposed by silver salts, yielding corresponding salts of platosemidiammonium. Soda removes hydrochloric acid from it, leaving a dingy-coloured powder which probably has the composition $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{OH}^{\text{H}} \\ \text{N}^{\text{H}}\text{H}^{\text{H}} \end{smallmatrix}\right. + \text{H}_2\text{O}$ (Cleve).

Bromide, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}}\text{Br} \\ \text{Br} \end{smallmatrix}\right.$.—Obtained on adding hydrobromic acid to the solution of the corresponding nitrate, in bulky yellow needles, quickly changing to a brick-red crystalline mass, which, by recrystallisation from boiling water, is again converted into yellow crystals.

The **iodide** crystallises in slender yellow needles. It unites with iodine to form a black periodide.

Cyanide.—Colourless needles. The **platinocyanide**, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}}\text{Cy} \\ \text{Cy} \end{smallmatrix}\right.$, $\text{PtCy}_2 + 3\text{H}_2\text{O}$, is a sulphur-yellow powder.

The **sulphocyanate**, isomeric with Buckton's platossammonium sulphocyanate (v. 513), forms golden-yellow flattened prisms, the solution of which is decomposed on boiling. It appears to react with nitromuriatic acid differently from the isomeric platossammonium sulphocyanate.

The **nitrate**, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}}(\text{NO}_3) \\ (\text{NO}_3) \end{smallmatrix}\right.$, obtained by decomposing the chloride with silver nitrate, forms whitish crusts made up of ill-defined crystals. Its solution mixed with hydrochloric acid deposits the corresponding chloride.

Nitrite, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}}(\text{NO}_2) \\ (\text{NO}_2) \end{smallmatrix}\right.$.—Lang obtained this salt by adding ammonia to platinum nitrite. It may also be prepared by double decomposition. It forms long silk needles which detonate when heated. Hot hydrochloric acid converts it into the corresponding chloride. Sulphurous acid converts it into an amorphous substance (Cleve).

Sulphate, $\text{Pt}^{\text{H}}\left\{\begin{smallmatrix} \text{N}^{\text{H}}\text{H}^{\text{H}} \\ \text{SO}_4 \end{smallmatrix}\right.$.—Yellowish-white crystalline crusts.

Chlorosulphite, $\text{Pt} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4\text{Cl} \\ \text{SO}^2\text{H} \end{smallmatrix} \right\}$.—Colourless, moderately soluble needles, obtained by passing a current of sulphur dioxide through a boiling solution of the chloride, and evaporating over the water-bath.

Double Sulphites.—The ammonium salt, $(\text{SO}^2)^2 \left\{ \begin{smallmatrix} (\text{NH}^4)^4 \\ (\text{PtN}^2\text{H}^4)^2 \end{smallmatrix} \right\}$, is obtained by dissolving the chloride in excess of ammonium sulphate. On adding alcohol the salt is precipitated in oily drops which soon crystallise. By recrystallisation it is obtained in slender needles.

The chlorinated ammonium sulphite, $(\text{SO}^2)^2 \left\{ \begin{smallmatrix} (\text{NH}^4)^2 \\ (\text{PtN}^2\text{H}^4\text{Cl})^2 \\ (\text{PtN}^2\text{H}^4)^2 \end{smallmatrix} \right\}$, is prepared like the preceding, excepting that the chloride must be kept in excess. It forms bulky, prismatic, very soluble crystals (Peyrono; Clevo).

The ammonium salt forms with barium and silver salts precipitates containing—

Oxalates.—The neutral oxalate obtained by the action of ammonium oxalate on platosemidiammonium nitrate forms colourless microscopic crystals containing—

3. Platosemonodiammonium Compounds, $\text{Pt}^{\text{R}} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4\text{R} \\ \text{NH}^4\text{R} \end{smallmatrix} \right\}$, or $(\text{N}^2\text{H}^4\text{Pt})^{\text{H}^2} \left\{ \begin{smallmatrix} \text{H}^2 \\ \text{H}^1 \end{smallmatrix} \right\} \text{N}^2\text{F}$

Chloride, $\text{Pt} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4\text{Cl} \\ \text{NH}^4\text{Cl} \end{smallmatrix} \right\}$.—Very soluble colourless needles or nacreous scales, obtained by the action of hydrochloric acid on the nitrate. Its solution mixed with potassium chloroplatinite yields the following salt:

Chloroplatinite, $2 \left[\text{Pt}^{\text{R}} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4\text{Cl} \\ \text{NH}^4\text{Cl} \end{smallmatrix} \right\} \right]. \text{Pt}^{\text{R}}\text{Cl}^2$.—This salt, polymeric with platosemonodiammonium chloride, $[=3\text{PtN}^2\text{H}^4\text{Cl}^2]$, constitutes the brown-red salt described by Peyrono (iv. 674). It is always formed in small quantity when ammonia is added to platinumous chloride. It is slightly soluble in cold, more soluble in boiling water. Treated with silver nitrate it yields silver chloroplatinite and platosemonodiammonium nitrate; with potassium permanganate and hydrochloric acid it yields rhombic tables of platosemonodiammonium chloride.

Nitrate, $\text{Pt} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4(\text{NO}^3) \\ \text{NH}^4(\text{NO}^3) \end{smallmatrix} \right\}$.—Ill-defined crystals, grouped in yellowish crusts; very soluble, and decomposing with violence when heated.

Sulphate, $\text{Pt} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4 \\ \text{NH}^4 \end{smallmatrix} \right\} \text{SO}^4$.—Moderately soluble snow-white crusts.

4. Platosediammonium Compounds, $\text{Pt}^{\text{R}} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^4\text{R} \\ \text{N}^2\text{H}^4\text{R} \end{smallmatrix} \right\}$, or $\text{N}^2 \left\{ \begin{smallmatrix} \text{H}^4 \\ \text{N}^2\text{H}^4\text{Pt}^{\text{R}} \end{smallmatrix} \right\} \text{R}^2$

This group includes Reiset's first chloride (tetrammonio-platinumous chloride, iv. 675), and its analogues. The chloride, treated with a solution of potassium chloroplatinite, yields the chloroplatinite of the series, which is the green salt of Magnus. This latter, treated with chlorine, yields platinodiammonium chloride (Gros' chloride), $\text{PtCl}^2.\text{N}^2\text{H}^4.\text{Cl}^2$; and with nitric acid the chloronitrate, $\text{Pt}(\text{NO}^3)^2.\text{N}^2\text{H}^4.\text{Cl}^2$.

Platosediammonium chloride forms double salts with certain metallic chlorides, especially with the chlorides of platinum. Such compounds have been obtained by Buckton and by Thomsen (1st Suppl. 953, 954). The copper salt, $\text{PtCl}^2(\text{N}^2\text{H}^4)^2\text{CuCl}^2$, described by Millon a. Commaille (iv. 675), may also be included in the same group.

Reiset described two salts as compounds of the chloride of this group with platinum tetrachloride, viz.: $\text{Pt}(\text{N}^2\text{H}^4)^2\text{Cl}^2.\text{PtCl}^4$, and $[\text{Pt}(\text{N}^2\text{H}^4)^2\text{Cl}^2]^2.\text{PtCl}^4$ (iv. 675); but according to Cleve these salts do not contain the tetrachloride of platinum, this compound being in fact reduced by Reiset's chloride. The first, which is red, gives, when digested with silver nitrate, chloroplatinite of silver, together with Raewsky's chlorodinitrate; it is therefore the chloroplatinite of platinodiammonium, $\text{Pt}(\text{NH}^4)^2\text{Cl}^2.\text{PtCl}^2$. The second is nothing but the green salt of Magnus, which is formed when the solutions used are dilute and boiling; in this case the solution contains Gros' chloride, $\text{PtCl}^2.\text{N}^2\text{H}^4.\text{Cl}^2$.

Platosediammonium Bromide, $\text{Pt}(\text{N}^2\text{H}^4)^2\text{Br}^2$, obtained by decomposing the sulphate with barium bromide, crystallises in colourless flattened prisms (in cubes

according to Reiset), very soluble, and containing 3 mols. H_2O , which they lose at 100° . The salt is not decomposed by boiling water (Cleve).

The *iodide*, $\text{Pt}(\text{N}^2\text{H}^4)^2\text{I}^2$, obtained like the bromide, crystallises in cubes. At the boiling heat it gives off 2NH_3 , and is converted into iodide of platossammonium.

Nitrate, $\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^4(\text{NO}^3) \\ \text{N}^2\text{H}^4(\text{NO}^3) \end{smallmatrix}\right\}$.—Obtained in colourless or yellow needles by the action of nitric acid on the chloride. It is slightly soluble in cold water; deflagrates like gunpowder. It unites directly with chlorine, bromine, and iodine, also with nitrogen tetroxide, with which it forms crystals of a fine indigo-colour. Strong nitric acid converts it into a trinitro-derivative (Cleve).

Hydroxide, $\text{Pt}(\text{N}^2\text{H}^4)^2(\text{OH})^2$.—Described in vol. iv. p. 675, as oxide.

Sulphates.—The *neutral sulphate*, $\text{Pt}(\text{N}^2\text{H}^4)^2\text{SO}^4$, crystallises in transparent rectangular octohedrons, which, according to Poyzner, are very slightly soluble in cold water, and dissolve in 50–60 pts. of boiling water. It unites with chlorine, &c. Nitrous acid converts it into nitroplatinammonium nitrate, $\text{N}^2\text{H}^4\text{Pt}^+(\text{NO}^2)(\text{NO}^3)$.

The *acid sulphate*, $(\text{N}^2\text{H}^4)^2\text{Pt}.\text{SO}^4 + 2(\text{N}^2\text{H}^4)^2\text{Pt}(\text{SO}^4\text{H})^2 + 8\text{H}_2\text{O}$, is precipitated in nacreous scales on adding sulphuric acid to a solution of platossammonium chloride (Cleve). Another acid sulphate was accidentally obtained by Cleve in colourless, very fragile prisms containing $2[(\text{N}^2\text{H}^4)^2.\text{Pt}.\text{SO}^4] + (\text{N}^2\text{H}^4)^2.\text{Pt}(\text{SO}^4\text{H})^2$.

Sulphite.—Acid sodium sulphite forms, with platossammonium chloride, a precipitate made up of colourless needles having the composition $3(\text{N}^2\text{H}^4)^2\text{PtSO}^3 + 2\text{PtSO}^3 + 4\text{H}_2\text{O}$. Its solution in hydrochloric acid gives the green salt of Magnus (Cleve).

Carbonates.—The *neutral carbonate*, $\text{Pt}(\text{N}^2\text{H}^4)^2\text{CO}^3 + \text{H}_2\text{O}$, is formed by decomposing the chloride with sodium carbonate or by exposing the hydrate to the air. On further exposure it absorbs an additional quantity of carbonic acid, and passes into the *acid carbonate*, $\text{Pt}(\text{N}^2\text{H}^4)^2(\text{CO}^2\text{H})^2$.

Chromates.—The *neutral salt*, $\text{Pt}(\text{N}^2\text{H}^4)^2\text{CrO}^4$, is a lemon-yellow nearly insoluble powder (Cleve). The *dichromate*, $\text{Pt}(\text{N}^2\text{H}^4)^2\text{Cr}_2\text{O}_7$, is a yellow precipitate slightly soluble in water, insoluble in alcohol, crystallising from boiling water in small cubes. Its ammoniacal solution, when left to evaporate, deposits crystals of the neutral chromate. By calcination it is resolved into chromic oxide, ammonia, water, nitrogen and platinum (Buckton).

Phosphate, $\text{Pt}(\text{N}^2\text{H}^4)^2.\text{PO}^4\text{H} + 2\frac{1}{2}\text{H}_2\text{O}$.—Flattened colourless prisms, soluble in water, precipitated by alcohol. Treated with bromine it yields the *bromide*, $\text{PtBr}^2(\text{N}^2\text{H}^4)^2.\text{Br}^2$, and the *brominated phosphates*, $(\text{N}^2\text{H}^4)^2(\text{PtBr}^2)\text{PO}^4$ and $(\text{N}^2\text{H}^4)^2(\text{PtBr}^2)(\text{PO}^4\text{H})^2 + 4\text{H}_2\text{O}$. It appears to form compounds with ammonium phosphate (Cleve).

Organic salts.—The *acetate*, $(\text{N}^2\text{H}^4)^2\text{Pt}(\text{C}^2\text{H}_3\text{O}^2)^2$, is colourless, very soluble, and crystallises in flattened prisms. The *benzoate*, $(\text{N}^2\text{H}^4)^2\text{Pt}(\text{C}^7\text{H}_5\text{O}^2)^2$, forms colourless scales. The *neutral tartrate*, $(\text{N}^2\text{H}^4)^2\text{Pt}.\text{C}^4\text{H}_4\text{O}^6 + 2\text{H}_2\text{O}$, is soluble and crystallisable. The *acid tartrate*, $(\text{N}^2\text{H}^4)^2\text{Pt}(\text{C}^4\text{H}_4\text{O}^6)^2$, crystallises in slender needles soluble in hot water. The *neutral oxalate* crystallises in small needles; the *acid oxalate* forms colourless soluble needles (Cleve).

5. **Platinammonium Compounds**, $\text{Pt}\begin{smallmatrix} \text{NH}^+\text{R} \\ \text{NH}^+\text{R} \end{smallmatrix}$. The *chloride* of this

series, discovered by Gerhardt, is obtained by the action of chlorine on platossammonium chloride. The same chemist likewise obtained the hydrate, the nitrate, the neutral sulphate, and the basic oxalate of the series (iv. 676).

The *bromide*, $\text{Br}^2\text{Pt}(\text{NH}^3)^2.\text{Br}^2$, is a heavy crystalline orange-red powder, composed like the chloride, of quadratic pyramids with truncated summits.

The *iodide*, $\text{IPt}(\text{NH}^3)^2.\text{I}^2$, is a black non-crystalline powder obtained by digesting platossammonium iodide with tincture of iodine. With ammonia it forms a crystalline powder containing $\text{Pt}^2(\text{NH}^3)^4\text{I}^4$. Treated with boiling potash-solution it furnishes a yellow powder of variable composition, which gives with hydriodic acid a black amorphous powder consisting of diplatinammonium iodide, $(\text{Pt}^2)(\text{NH}^3)^4\text{I}^4$. This last compound, treated successively with potash and with hydriodic acid gives $(\text{Pt}^2)(\text{NH}^3)^4\text{I}^4$, which in its turn furnishes a still more condensed iodid $(\text{Pt}^2)(\text{NH}^3)^4\text{I}^4$. These iodides—whose existence, however, is not quite established—would form a homologous series, $\text{Pt}^2(\text{NH}^3)^4\text{I}^{4+2}$, the first term of which is the iodide of platinammonium (Cleve).

Hydroxide, $(\text{OH})^2\text{Pt}(\text{NH}^3)^2(\text{OH})^2$.—Described (iv. 676) as oxide. Obtained by treating platinammonium nitrate with excess of ammonia.

Nitrates.—A *basic nitrate*, $(\text{HO})^2\text{Pt}(\text{NH}^2)^2(\text{NO}^2)^2 + 2\text{H}^2\text{O}$, is obtained from the chloride by double decomposition. Nitric acid converts it into the *normal nitrate*, $(\text{NO}^2)^2\text{Pt}(\text{NH}^2)^2(\text{NO}^2)^2$ (iv. 676).

Nitrites.—*Nitronitrite*, $(\text{NO}^2)^2\text{Pt}(\text{NH}^2)^2(\text{NO}^2)^2$. Obtained by the action of boiling nitric acid on platosammonium nitrite, and separated, on evaporation, in large colourless plates. With potassium iodide it yields a precipitate of platinumammonium iodide (Clove).

Chloronitric Nitrite, $(\text{NO}^2)\text{ClPt}(\text{NH}^2)^2(\text{NO}^2)^2$.—Precipitated in rhombic scales on adding hydrochloric acid to a solution of the preceding salt (Clove).

Dichloronitrite, $\text{Cl}^2\text{Pt}(\text{NH}^2)^2(\text{NO}^2)^2$.—Deposited in shining scales on adding hydrochloric acid to the boiling solution of the nitronitrite. Its solution is not precipitated by silver nitrate; but on adding silver nitrite to its hot solution, small rhombic plates are formed consisting of a double nitrite, $(\text{NO}^2)^2\left\{\begin{smallmatrix} (\text{NH}^2)^2\text{PtCl}^2 \\ \text{Ag}^2 \end{smallmatrix}\right.$ (Clove).

The *dibromonitrite* forms microscopic rhombic plates very slightly soluble in water.

Dichlorinated Chloronitrite, $\text{Cl}^2\text{Pt}\left\{\begin{smallmatrix} \text{NH}^2(\text{NO}^2) \\ \text{NH}^2\text{Cl} \end{smallmatrix}\right.$.—Small yellow crystals deposited on adding potassium chloroplatinite to the nitronitrite.

The *sulphate*, $\text{SO}^4\text{Pt}(\text{NH}^2)^2\text{SO}^4$, is a yellowish mass which by solution in water is converted into the *basic sulphate*, $(\text{OH})^2\text{Pt}(\text{NH}^2)^2\text{SO}^4 + \text{H}^2\text{O}$, which is deposited in sparingly soluble crusts.

Oxalates.—The *neutral oxalate* contains $\text{C}^2\text{O}^4\text{Pt}(\text{NH}^2)^2\text{C}^2\text{O}^4$. The *basic oxalate*, $(\text{OH})^2\text{Pt}(\text{NH}^2)^2\text{C}^2\text{O}^4$, is a yellow precipitate which crystallises in laminae from boiling water and detonates by heat (Gerhardt).

6. Platinosemidiammonium Compounds, $\text{R}^2\text{Pt}\left\{\begin{smallmatrix} (\text{N}^2\text{H}^2)\text{R}^* \\ \text{R} \end{smallmatrix}\right.$.—These com-

pounds, isomeric with those of the last group, have been described by Blomstrand and y Clove (*Bull. Soc. Chim.* [2], xvii. 105).

Chloride, $\text{Cl}^2\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^2\text{Cl} \\ \text{Cl} \end{smallmatrix}\right.$.—Obtained by the action of chlorine on the chloride of platosemidiammonium (p. 994). It crystallises in six-sided rhombic leaflets, yellow and anhydrous, soluble in 300 pts. of cold water, and in 65 pts. of boiling water. At 60° it becomes olive-green. It is not decomposed by strong sulphuric acid. Potash dissolves it with evolution of ammonia. Sulphurous acid reduces it to chlorosulphite of platosemidiammonium.

The *bromide*, $\text{Br}^2\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^2\text{Br} \\ \text{Br} \end{smallmatrix}\right.$, is red, but in other respects resembles the chloride.

Polyiodide, $\text{I}^2\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^2\text{I}^2 \\ \text{I} \end{smallmatrix}\right. = \text{Pt}(\text{N}^2\text{H}^2)\text{I}^6$.—Obtained by the action of iodine on the chloride of platosemidiammonium (p. 994). Octohedral crystals forming a nearly black powder; soluble with purple colour.

Nitrate, $(\text{OH})^2\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^2\text{NO}^2 \\ \text{OH} \end{smallmatrix}\right.$.—On treating the chloride with silver nitrate, and adding alcohol to the filtered liquid, a precipitate is obtained which appears to have this composition. The normal nitrate has not been obtained.

Chloronitrite, $\text{Cl}^2\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^2\text{NO}^2 \\ \text{NO}^2 \end{smallmatrix}\right.$.—Long, pale-yellow, very fragile needles, obtained by the action of chlorine on the nitrite of platosemidiammonium (Blomstrand). Silver nitrate removes only half the chlorine.

The corresponding *bromonitrite* forms orange-coloured needles which react in like manner in silver salts.

A *basic chloronitrite*, $\text{Cl}^2\text{Pt}\left\{\begin{smallmatrix} \text{N}^2\text{H}^2\text{NO}^2 \\ \text{OH} \end{smallmatrix}\right.$, is obtained by boiling the normal chloronitrite with silver nitrite. It crystallises in pale-yellow needles.

* The groups, $\text{N}^2\text{H}^2 = \text{NH}^2(\text{NH}^2)$, which figure in all these formulae, are bivalent, as in the series 3. and 4. One of their nitrogen-atoms is directly combined, on one side with the platinum, on the other with the nitrogen, of a group NH^2 . For this reason the group N^2H^2 must not be confounded with the group $(\text{NH}^2)^2$, which exists in the compounds of platosammonium and platinumammonium.

Sulphate, $(\text{OH})^2\text{Pt} \begin{matrix} \nearrow \text{N}^2\text{H}^4 \\ \searrow \text{SO}^4 \end{matrix}$.—Yellow viscous mass obtained by double decomposition.

7. Platinomonodiammonium Compounds, $\text{R}^2\text{Pt} \begin{matrix} \nearrow \text{N}^2\text{H}^4\text{R} \\ \searrow \text{NH}^2\text{R} \end{matrix}$.

Chloride, $\text{Cl}^2\text{Pt} \begin{matrix} \nearrow \text{N}^2\text{H}^4\text{Cl} \\ \searrow \text{NH}^2\text{Cl} \end{matrix}$.—Formed by the action of nitromuriatic acid on chloride of platomonodiammonium. Rhombic or hexagonal scales.

Basic Nitrate, $(\text{OH})^2\text{Pt} \begin{matrix} \nearrow (\text{N}^2\text{H}^4)(\text{NO}^3) \\ \searrow (\text{NH}^2)(\text{NO}^3) \end{matrix}$ + H^2O .—Microscopic crystals deposited on concentrating the solution obtained by boiling the following salt with silver nitrate.

Dibromonitrate, $\text{Br}^2\text{Pt} \begin{matrix} \nearrow (\text{N}^2\text{H}^4)(\text{NO}^3) \\ \searrow (\text{NH}^2)(\text{NO}^3) \end{matrix}$ + H^2O .—Soluble yellow crusts obtained by adding bromine to platomonodiammonium nitrate (p. 995). The *monobromonitrate* is obtained by boiling this salt with a quantity of silver nitrate just sufficient to remove half the bromine.

Bromosulphate, $\text{Br}^2\text{Pt} \begin{matrix} \nearrow \text{N}^2\text{H}^4 \\ \searrow \text{NH}^2 \end{matrix} \text{SO}^4$.—Bright-yellow crusts obtained by adding bromine to platomonodiammonium sulphate (Cleve, *Bull. Soc. Chim.* [2], xvii. 107).

8. Platinodiammonium Compounds, $\text{R}^2\text{Pt} \begin{matrix} \nearrow \text{NH}^2(\text{NH}^4)\text{R} \\ \searrow \text{NH}^2(\text{NH}^4)\text{R} \end{matrix}$ or

$\text{R}^2\text{Pt} \begin{matrix} \nearrow (\text{N}^2\text{H}^4)\text{R} \\ \searrow (\text{N}^2\text{H}^4)\text{R} \end{matrix}$. Several of these compounds were discovered by Gros and by

Raewsky (iv. 675) and numerous others have been obtained by Cleve. They are formed by addition of an electronegative element to the platomonodiammonium compounds, or by the oxidation of the latter. One half of the electro-negative element or radicle contained in these compounds—that half, namely, which is directly united to the platinum—is difficult to remove, or cannot be removed at all by double decomposition; such, for example, is the case with the chlorine in Gros' salts, which can only be partially replaced by the action of silver salts.

Chloride, $\text{Cl}^2\text{Pt} \begin{matrix} \nearrow \text{N}^2\text{H}^4\text{Cl} \\ \searrow \text{N}^2\text{H}^4\text{Cl} \end{matrix}$.—This is Gros' chloride (iv. 676), obtained by treating the corresponding nitrate with hydrochloric acid, or by passing chlorine into a solution of platomonodiammonium chloride.

A *basic chloride*, $(\text{OH})\text{ClPt}(\text{N}^2\text{H}^4)^2\text{Cl}^2$, is obtained in microscopic insoluble needles by adding sal-ammoniac to a solution of the basic monochloronitrate.

Raewsky's Chloride, $\text{PtCl}^2\text{O}(\text{N}^2\text{H}^4)^2\text{Cl}^2$ (?).—Obtained by decomposing the basic chloronitrate, $\text{Pt}^2(\text{Cl}^2\text{O})(\text{N}^2\text{H}^4)^2\text{O}^2(\text{NO}^3)^2$ (iv. 677), with excess of hydrochloric acid. It is moderately soluble in cold and much more soluble in boiling water; less soluble in hydrochloric acid, which renders its aqueous solution turbid.

The *chloroplatinite* and *chloroplatinate* are formed by adding sodium chloroplatinite or chloroplatinate to platinodiammonium dichloronitrate.

Bromide, $\text{Br}^2\text{Pt}(\text{N}^2\text{H}^4)^2\text{Br}^2$.—Slightly soluble microscopic needles precipitated or adding a soluble bromide to the nitrate of dibromoplatinodiammonium. When boiled with solution of silver nitrate it yields silver bromide, and a solution which on cooling deposits yellow, slightly soluble crystals, probably a basic bromonitrate (Cleve).

The *basic bromide*, $(\text{OH})\text{BrPt}(\text{N}^2\text{H}^4)\text{Br}^2$, obtained like the basic chloride, is a pale yellow crystalline precipitate.

Iodide, $\text{I}^2\text{Pt}(\text{N}^2\text{H}^4)^2\text{I}^2$.—Graphitoidal powder converted by ammonia into yellow crystalline powder containing $\text{Pt}(\text{NH}^2)^2(\text{NH}^4)^2\text{I}^2$ + H^2O , or more probably $\text{I}^2(\text{Pt})^2 \begin{matrix} \nearrow (\text{N}^2\text{H}^4)^2\text{I}^2 \\ \searrow (\text{N}^2\text{H}^4)^2\text{O}^2 \end{matrix}$.

Chlorobromide, $\text{BrClPt}(\text{N}^2\text{H}^4)^2\text{BrCl}$.—Raewsky obtained this salt by treat-

platosediammonium chloride with bromine (iv. 676). It may also be formed by double decomposition, either between ammonium chloride and platinodiammonium dibromonitrate, or between ammonium bromide and platinodiammonium dichloronitrate. It is a yellow precipitate which, when treated with hydrochloric acid, exchanges part of its bromine for chlorine, and gives with silver nitrate a mixture of silver chloride and bromide, and of the two salts, $(\text{OH})\text{BrPt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$ and $(\text{OH})\text{ClPt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$. A compound containing 1 at. bromine to 3 at. chlorine is obtained by precipitating the basic bromonitrate with hydrochloric acid (Cleve).

The *chloriodides*, formed under similar conditions, do not appear to be of constant composition. One containing $(\text{ClPt})\text{Pt}(\text{N}^2\text{H}^2)^2\text{Cl}^2$ is obtained in small brown octahedrons by the action of hydriodic acid on the iodonitrate of diplatinotetradiammonium (Cleve).

The *basic chlorobromides*, $(\text{OH.Cl})\text{Pt}(\text{N}^2\text{H}^2)^2\text{Br}^2$ and $(\text{OH.Br})\text{Pt}(\text{N}^2\text{H}^2)^2\text{Cl}^2$, are crystalline precipitates (Cleve).

Ferrocyanide.—Gros' nitrate, $\text{Cl}^2\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$, treated with solution of potassium ferrocyanide, yields a violet precipitate, which appears to have the composition, $(\text{FeCy}^2\text{K})[\text{PtO}(\text{N}^2\text{H}^2)^2\text{Cy}^2]^2$. The mother-liquors yield the platosediammonium cyanide analogous to the green salt of Magnus.

The *chlorosulphocyanate*, $\text{Cl}^2\text{Pt}(\text{N}^2\text{H}^2)^2(\text{CNS})^2$, is an orange-coloured crystalline precipitate.

Nitrates.—The *normal nitrate*, $(\text{NO}^2)^2\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$, is not known.

The *basic nitrate*, $(\text{OH.NO}^2)\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$ (Gerhardt's oxy-nitrate, iv. 677), is formed by the action of nitric acid on platosediammonium nitrate; also by the action of silver nitrate on the iodonitrate. It is a white very soluble crystalline powder. Treated with ammonia it yields the bibasic nitrate, $(\text{OH})^2\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$, which forms a white amorphous powder detouring when heated and turned blue by sulphuric acid. Hydrochloric acid converts it into Gros' chloride.

Dinitronitrate, $(\text{NO}^2)^2\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$.—This salt is formed under various circumstances, especially by the action of nitrous vapours on platosediammonium sulphate. It is precipitated in small well-defined octahedrons of an indigo-blue colour, which decompose when dissolved in water, giving off nitrous vapours.

Chloronitrates: a. $(\text{Cl.NO}^2)\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$.—White crystalline precipitate formed on adding nitric acid to the solution of the following salt. Decomposed by water into acid and the basic salt *b*.

b. $(\text{OH.Cl})\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$.—White microscopic slightly soluble crystals, obtained by the action of silver nitrate on the salt *c*. Prolonged boiling with silver nitrate is required to remove the chlorine. Cleve, who prepared this salt, regards it as identical with one of Raewsky's nitrates (iv. 677).

c. $\text{ClPt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$ (Gros' nitrate, iv. 677).—Obtained by boiling the green salt of Magnus with strong nitric acid; also by the action of chlorine on nitrate of platosediammonium.

d. $(\text{NO}^2)^2\text{Pt}(\text{N}^2\text{H}^2)^2\text{Cl}^2$.—This salt, isomeric with the preceding, is distinguished from it by the fact that its chlorine is easily precipitated by silver nitrate, whereas the group $(\text{NO}^2)^2$, which is united with the platinum, is not removed by double decomposition; Gros' nitrate, on the contrary, gives scarcely any precipitate with silver nitrate, even after a long time. The salt *d* is obtained by the action of hydrochloric acid on a boiling solution of the basic nitrate of platinodiammonium. It is then deposited as a white powder made up of small right prisms; when recrystallised by slow evaporation it forms large crystals containing H^2O . With platinic chloride it forms an orange-red double salt containing $(\text{NO}^2)^2\text{Pt}(\text{N}^2\text{H}^2)^2\text{Cl}^2 + \text{PtCl}^4 + 2\text{H}^2\text{O}$ (Cleve).

Raewsky's Nitrates.—By boiling the green salt of Magnus with a large excess of nitric acid, Raewsky obtained two salts whose composition he represented by the formulæ:

The first, which is but slightly soluble in nitric acid, separates in small shining crystals, and the second crystallises with difficulty from the mother-liquor. These salts form the points of departure of two series, a few members of which were obtained by Raewsky. Their constitution, supposing the analyses to be correct, is very difficult to determine. Gerhardt supposed them each to contain 2 at. oxygen less, and regarded them as sesqui-acid salts of diplatinamine (iv. 677). They probably belong to the diplatinodiammonium group.

Bromonitrates (Cleve, loc. cit.)—*a.* $(\text{Br.NO}^2)\text{Pt}(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$. Orange-coloured

crystalline powder, decomposable by water, obtained by the action of nitric acid on the boiling solution of the following salt.

b. $(\text{Br} \cdot \text{OH})\text{Pt}(\text{N}^2\text{H}^4)(\text{NO})^2$. Pale yellow, slightly soluble granular salt, obtained by the action of silver nitrate on the salt c.

c. $\text{Br}^2\text{Pt}(\text{N}^2\text{H}^4)(\text{NO})^2$ (*Brominated salt of Gros*). Prepared like the corresponding chloronitrate. Crystallises in lemon-yellow soluble flattened prisms. When boiled with silver nitrate it gives up half of its bromine and is converted into the salt b.

* *Iodonitrate*, $\text{IPt}(\text{N}^2\text{H}^4)(\text{NO})^2$.—Prepared by the action of iodine on platino-ammonium nitrate. Nearly black crystals of the same form as the chloronitrate. Silver nitrate at the boiling heat removes half the iodine, forming the basic iodonitrate. Ammonia precipitates from its solution a dingy yellow powder formed of microscopic needles, and constituting perhaps, according to Cleve, the oxyiodonitrate of diplatinetetradiammonium.

Nitro-iodonitrate, $(\text{NO})_2\text{IPt}(\text{N}^2\text{H}^4)(\text{NO})^2$.—Orange-brown crystals obtained by the action of nitric acid on the oxy-iodide of diplatinetetradiammonium (Cleve).

Carbonates.—a. $[(\text{NO})_2\text{Pt}(\text{N}^2\text{H}^4)]^2(\text{CO}_3)^2$ (?). White crystalline powder obtained by adding ammonia sesquicarbonate to the basic nitrate.

b. $[\text{BrPt}(\text{N}^2\text{H}^4)]^2(\text{CO}_3)^2 + 4\text{H}_2\text{O}$. Yellow crystalline powder obtained in the same way as the dibromonitrate. It unites with the dibromonitrate, forming a double salt which crystallises in yellow microscopic prisms.

c. A compound of the monochlorocarbonate with Gros' chloronitrate is obtained by pouring a solution of the latter into a boiling solution of ammonium carbonate.

d. $(\text{OH} \cdot \text{Cl})\text{Pt}(\text{N}^2\text{H}^4)\text{CO}_2$. Formed by adding Gros' nitrate to excess of sodium carbonate (Cleve).

e. *Raewsky's Carbonate*, $(\text{O} \cdot \text{Cl})^2\text{Pt}^2(\text{N}^2\text{H}^4)_2\text{O}_2(\text{CO}_3)^2$.—White granular, very soluble precipitate (iv. 678).

Sulphates.—The *neutral sulphate*, $(\text{SO}_4\text{Pt})(\text{N}^2\text{H}^4)_2\text{SO}_4 + 2\text{H}_2\text{O}$, is a white amorphous powder formed by the action of sulphuric acid on the basic nitrate.

A *basic sulphate*, $\text{SO}_4\left\{\begin{array}{l} \text{Pt}(\text{OH})\text{N}^2\text{H}^4 \cdot \text{N}^2\text{H}^4 \cdot \text{SO}_4 \\ \text{Pt}(\text{OH})\text{N}^2\text{H}^4 \cdot \text{N}^2\text{H}^4 \cdot \text{SO}_4 \end{array}\right. + 3\text{H}_2\text{O}$, is obtained by precipitating a hot solution of the neutral bromonitrate with silver sulphate, and evaporating the filtrate. Colourless flattened prisms, soluble in water. Barium chloride throws down from its solution only a third of the sulphuric acid, showing that part of this acid is contained in the radicle (Cleve). This salt yields, by double decomposition, a series of salts, the *hydroxyl-sulphoplatodiammonium salts*, containing non-precipitable sulphuric acid (*infra*).

Another basic sulphate is formed, according to E. Davy, on boiling a solution of platonic sulphate neutralised with ammonia. It is precipitated as a light brown powder, slightly explosive, insoluble in water, soluble in acids.

Chlorosulphate, $\text{ClPt}(\text{N}^2\text{H}^4)_2\text{SO}_4$ (see iv. 677).

Monochloro-trisulphate, $\text{PtCl}\left\{\begin{array}{l} \text{SO}_4 \\ \text{PtCl} \end{array}\right\}\left\{\begin{array}{l} (\text{N}^2\text{H}^4)_2\text{SO}_4 \\ (\text{N}^2\text{H}^4)_2\text{SO}_4 \end{array}\right.$ —Delicate prisms obtained by treating Gros' chlorocarbonate with sulphuric acid (Cleve).

Bromosulphate, $\text{BrPt}(\text{N}^2\text{H}^4)_2\text{SO}_4$.—Lemon-yellow, very soluble, crystalline powder. Its solution, mixed with a quantity of silver nitrate sufficient to precipitate only half the bromine, yields a solution which deposits yellow needles having the composition $\text{PtBr}\left\{\begin{array}{l} (\text{N}^2\text{H}^4)_2\text{SO}_4 \\ \text{PtBr} \end{array}\right\}\left\{\begin{array}{l} (\text{N}^2\text{H}^4)_2\text{SO}_4 \\ (\text{N}^2\text{H}^4)_2\text{SO}_4 \end{array}\right.$ From this salt barium chloride throws down two-thirds of the sulphuric acid.

Iodosulphate, $\text{IPt}(\text{N}^2\text{H}^4)_2\text{SO}_4$.—Brown crystalline powder slightly soluble in water.

Chloronitric and Bromonitric Sulphates.—These salts are obtained in the crystalline state by dissolving the monochloro- or monobromo-nitrate in sulphuric acid, and pouring the solution into water. The former, $(\text{Cl} \cdot \text{NO})\text{Pt}(\text{N}^2\text{H}^4)_2\text{SO}_4 + \text{H}_2\text{O}$, is white; the latter, which contains Br in place of Cl, is yellow (Cleve).

HYDROXYLSULPHOPLATODIAMMONIUM COMPOUNDS (Cleve, *Bull. Soc. Chim.* [2], xv. 162). These compounds are derived from the basic sulphate, $\text{SO}_4[\text{Pt}(\text{OH})(\text{N}^2\text{H}^4)\text{SO}_4]^2 + 3\text{H}_2\text{O}$, above described, which contains the group SO_4 in direct combination with platinum, and not removable by double decomposition with barium salts. They may be supposed to contain the univalent radicle:

Chloride, $[\text{PtOH.SO}^4(\text{N}^2\text{H}^5)^2]\text{Cl} + 2\text{H}^2\text{O}$.—Obtained by decomposing the basic sulphate above mentioned with barium chloride. Forms colourless truncated prisms soluble in water. The solution mixed with hydrochloric acid deposits the salt in the anhydrous state. The chlorine of this salt is precipitated by silver nitrate, but the sulphuric acid is not precipitated by barium chloride.

The corresponding *chloroplatinate* forms orange-coloured flattened crystals, containing $2\text{H}^2\text{O}$.

Bromide.—Obtained like the chloride, and likewise contains $2\text{H}^2\text{O}$. Flattened crystals, colourless or yellowish.

Nitrate, $[\text{PtOH.SO}^4(\text{N}^2\text{H}^5)^2]\text{NO}^3$.—White crystalline, slightly soluble powder.

Sulphate.—Already described (p. 1000).

Chromates.—The *neutral salt*, $[\text{PtOH.SO}^4(\text{N}^2\text{H}^5)^2]^2\text{CrO}^4 + 2\text{H}^2\text{O}$, obtained like the chloride, forms rounded groups of yellow crystals. The *dichromate* is an orange-coloured, sparingly soluble precipitate.

Oxalate, $[\text{PtOH.SO}^4(\text{N}^2\text{H}^5)^2]^2\text{C}^2\text{O}^4 + 2\text{H}^2\text{O}$.—Crystalline precipitate.

On attempting to prepare the corresponding *hydroxide*, $[\text{PtOH.SO}^4(\text{N}^2\text{H}^5)^2]\text{OH}$, by the action of baryta on the sulphate, a colourless alkaline solution was obtained, which, on evaporation, suddenly yielded colourless sparingly soluble crystals, consisting of an isomeric form of this hydroxide, viz.: the *basic sulphate*, $\text{SO}^4\text{Pt}(\text{OH})^2(\text{N}^2\text{H}^5)^2$.

Platinodiammonium Chromates.—Cleve has examined the following chromates, all of which form yellow or orange-coloured crystallisable precipitates. They are obtained by double decomposition:

Platinodiammonium Phosphates.—Gros, by adding an alkaline phosphate to the dichloronitrate of this series, obtained small shining transparent crystals, very slightly soluble in water. Cleve has obtained the following salts:

- a. $\text{Pt}(\text{NO}^3)(\text{N}^2\text{H}^5)^2.\text{PO}^4 + \text{H}^2\text{O}$
- b. $\text{PtCl}^2(\text{N}^2\text{H}^5)^2.\text{PO}^4 + 2\text{H}^2\text{O}$
- c. $\text{PtBr}^2(\text{N}^2\text{H}^5)^2.\text{PO}^4 + 2\text{H}^2\text{O}$
- d. $\text{PtBr}^2(\text{N}^2\text{H}^5)^2(\text{PO}^4\text{H}^2)^2 + 2\text{H}^2\text{O}$
- e. $[\text{Pt}(\text{NO}^3)(\text{OH})(\text{N}^2\text{H}^5)^2]^2\text{C}^2\text{O}^4 + \text{H}^2\text{O}$.

The salts *a* and *c* are obtained by adding disodic phosphate, or the pyrophosphate, to the basic nitrate of platinodiammonium; *b* and *c* in like manner from the chloro- or bromo-nitrate of Gros. They are crystalline and slightly soluble. Lastly *d* is obtained by adding bromine to the phosphate of platodiammonium; it is moderately soluble and crystallises in lemon-yellow flattened prisms.

Racwsky's Phosphate, $\text{Pt}^2(\text{Cl}^2\text{O}).(\text{N}^2\text{H}^5)^4\text{O}^2.(\text{PO}^4\text{H}^2)^2$, separates in crystalline tufts on mixing hot strong solutions of the corresponding chloronitrate and trisodic phosphate (iv. 677).

Platinodiammonium Oxalates (iv. 677, 678).—Gros' *oxalate*, $\text{PtCl}^2(\text{N}^2\text{H}^5)^2\text{C}^2\text{O}^4$, is a white, crystalline, very soluble powder, obtained by double decomposition with Gros' nitrate and ammonium oxalate. The corresponding brominated salt is yellow.

Racwsky's Oxalate, $\text{Pt}^2(\text{Cl}^2\text{O})(\text{N}^2\text{H}^5)^4\text{O}^2(\text{C}^2\text{O}^4)^2$, is a white crystalline precipitate nearly insoluble in boiling water.

The *mononitric oxalate*, $\text{Pt}(\text{OH.NO}^3)(\text{N}^2\text{H}^5)^2\text{C}^2\text{O}^4$, is obtained in white flocks on adding ammonium oxalate to basic nitrate of platinodiammonium. It detonates when heated (Gerhardt).

ACETHYDROXYL-PLATINODIAMMONIUM COMPOUNDS (Cleve).—Bromo-sulphate of platinodiammonium, decomposed by basic lead acetate, yields a *basic acetate-sulphate*—

in which the group SO^4 may be replaced by double decomposition. It may accordingly be supposed to contain the radicle $[\text{Pt}(\text{OH.C}^2\text{H}^3\text{O}^2)(\text{N}^2\text{H}^5)^2]^2$, which for shortness may be represented by the symbol R.

Chloride, $2\text{ROCl}^2 + \text{H}^2\text{O}$.—Small, colourless, moderately soluble needles. Silver nitrate removes the whole of the chlorine. The *chloroplatinate*, $\text{PtCl}^2\text{R} + 2\text{H}^2\text{O}$, crystallises in orange-red, moderately soluble needles.

Nitrate, $R(NO^3)^2 + H^2O$.—White crystalline powder, slightly soluble in cold water.

Sulphate, $2(SO^4.R) + 3H^2O$.—This salt, whose formation is given above, is deposited on evaporation in rather large, well-defined, colourless crystals.

Dichromate, $Cr_2O^7.R + H^2O$.—Orange-coloured precipitate, which gives off its water at 100° .

9. **Diplatinoammonium**, $=(Pt^2)^2(NH^3)^4$.—The only known compound of this radicle is the iodide $I^2Pt^2(NH^3)^4I^2$, which is a crystalline powder obtained by the action of ammonia on the iodide of platinammonium, $I^2Pt(NH^3)^2I^2$ (p. 996).

10. **Diplatiosodiammonium**, $=(Pt^2)^2(N^2H^3)^2$, or $=(Pt^2)^2 \begin{matrix} (NH^2NH^3) \\ (NH^2NH^3) \end{matrix}$ (Cleve,

Bull. Soc. Chim. [2], xvii. 100).—When the chloride of platosemidiammonium is boiled with soda, a greyish, pseudomorphic, crystalline, insoluble powder is obtained, which detonates violently when heated. This powder, which forms black compounds with acids, constitutes the hydroxide of diplatiosodiammonium or of diplatino-semidiammonium:

The first of these formulæ was proposed by Blomstrand, the second by Cleve, who discovered this base and its salts. The difference of H^2 between the two formulæ is too small to be detected by analysis. Cleve bases his opinion on the formation of this hydroxide, which, if Blomstrand's view were correct, should take place according to the equation:

Conversely, the action of hydrochloric acid on the hydroxide, which ultimately produces the chloride of platosemidiammonium, ought to be attended with disengagement of hydrogen. Cleve, however, has never observed either oxidation or disengagement of oxygen in the first case, or disengagement of hydrogen in the second. Nitromuriatic acid transforms the hydroxide into diplatino-diammonium chloride, $(Pt^2)^2(N^2H^3)^2Cl^4$.

Diplatino-semidiammonium Chloride, $Cl^4Pt^2(NH^2.NH^3)^2$.—The hydroxide just described is converted by hydrochloric acid into a yellow powder which boiling water converts into a black powder, while chloride of platino-semidiammonium passes into solution. The black substance is the chloride of platinosemidiammonium.

Nitrate, $(NO^3)^2Pt^2(NH^2.NH^3)^2$.—Black, amorphous, insoluble powder, which detonates violently when heated.

Sulphate, $SO^4.Pt^2(NH^2.NH^3)^2$.—Black insoluble powder.

11. **Diplatino-diammonium Compounds**, $R^4(Pt^2)^2 \begin{Bmatrix} NH^3(NH^2) \\ NH^3(NH^2) \end{Bmatrix}$ The only

compound of this series yet obtained is the *chloride*, $Cl^4Pt^2(NH^2.NH^3)^2 + H^2O$, which is a yellow amorphous powder formed by the action of nitromuriatic acid on the hydroxide of the preceding series (Cleve).

12. **Diplatino-tetradiammonium Compounds**, $R^4(Pt^2)^2(N^2H^3)^4R^4$ (Cleve, *Bull. Soc. Chim.* [2], xv. 168). Racwsky's salts (iv. 677) may be included in this series.

Iodide, $I^2Pt^2(N^2H^3)^4I^2$.—Black powder obtained by adding potassium iodide to the iodonitrate.

Nitrates: *Iodonitrate*, $I^2Pt^2(N^2H^3)^4(NO^3)^4$.—Produced by the action of nitric acid on the oxydo-nitrate of diplatino-tetradiammonium (*infra*), according to the equation:—

It is an orange-coloured powder which dissolves in hot water and crystallises in small prisms. It contains 8 or 4 mols. of water which it gives off at 100° . Its solution is not precipitated by silver nitrate in the cold, but on heating the liquid, silver iodide is

* The formula $NH^2.NH^3$ is that of ammonium in which 1 at. of hydrogen is replaced by acid-oxygen.

slowly deposited. With ammonia it gives a precipitate of the oxyiodonitrate. Hydrochloric acid converts it into a brown crystalline powder consisting of chloriodoplatinodiammonium chloride, $\text{Pt}(\text{OII})(\text{N}^2\text{H}^2)^2\text{Cl}^2$. Bromine decomposes the iodonitrate, liberating the iodine and forming several products, and amongst others, yellow microscopic prisms having the composition $(\text{PtI})^2(\text{NH}^2)^2(\text{NO}^2)\text{Br}^2$.

The iodonitrate yields, by double decomposition, the three following salts:—

Iodosulphate, $\text{I}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{SO}^2)^2$.—Yellow, amorphous, insoluble powder.

Iodophosphate, $\text{I}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{PO}^2\text{H})^2$.—Yellow precipitate, formed of microscopic needles.

Iodoxalate, $\text{I}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{C}^2\text{O}^2)^2$.—Bulky yellow powder.

Basic Nitrate, $(\text{HO})^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$.—Formed by boiling the oxyiodonitrate with silver nitrate, and deposited gradually from the colourless solution as a white crystalline powder, very slightly in cold water, detonating violently when heated. It contains 2 mols. H_2O , which it gives off at 100° .

The *neutral nitrate*, $(\text{NO})^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2 + 4\text{H}_2\text{O}$, is formed by adding nitric acid to the basic nitrate. Resolved by water into nitric acid and the basic nitrate.

The *basic nitrate* yields by double decomposition the following salts:—

Chloride, $(\text{OH})^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2\text{Cl}^2 + \text{H}_2\text{O}$.—White microscopic needles very slightly soluble, completely decomposed by silver nitrate.

Sulphate, $(\text{OH})^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{SO}^2)^2 + 2\text{H}_2\text{O}$.—White amorphous powder.

Orthophosphate, $(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{PO}^2)^2 + 2\text{H}_2\text{O}$.—Bulky white powder.

Dichromate, $(\text{OH})^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{Cr}^2\text{O}^2)^2$.—Orange-coloured precipitate.

Oxalate, $(\text{HO})^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{C}^2\text{O}^2)^2 + 2\text{H}_2\text{O}$.—White precipitate.

Bromonitrate, $\text{Br}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2 + 2\text{H}_2\text{O}$.—Formed by adding bromine to the basic nitrate. Small yellow crystals moderately soluble in hot water. The solution does not precipitate silver nitrate. Ammonia throws down from it a yellow crystalline powder consisting of a bromodinirate. The bromonitrate yields by double decomposition the three following salts:—

Bromochloride, $\text{Br}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2\text{Cl}^2$.—Yellowish-white precipitate, formed of microscopic needles.

Bromosulphate, $\text{Br}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2(\text{SO}^2)^2 + 2\text{H}_2\text{O}$.—Yellowish-white precipitate, giving off its water at 100° .

Acid Bromoxalate, $\text{Br}^2(\text{Pt}^2)(\text{N}^2\text{H}^2)^2\left\{\frac{\text{C}^2\text{O}^2}{(\text{C}^2\text{O}^2\text{H})^2}\right\}$.—White precipitate composed of microscopic needles.

This is the yellow powder formed by the action of ammonia on platinumammonium iodide (p. 998). Nitric acid attacks it, giving off vapours of iodine, and forming the nitroiodonitrate of platinodiammonium, $\text{Pt}^2(\text{NO}^2\text{I})(\text{N}^2\text{H}^2)^2(\text{NO}^2)^2$.

—Yellow microscopic needles obtained by the action of ammonia on the iodonitrate of platinodiammonium (p. 1000). Nitric acid converts it into the iodonitrate of diplatinotetradiammonium above described.

To these oxidised compounds probably belong Rasowsky's salts (iv. 677, 678), although they are said to contain 2 or 3 atoms of oxygen, which is doubtful.

Ammoniacal Platinum-Compounds containing Organic Radicles.

The methylamine and ethylamine salts, $\text{PtCl}^2(\text{CH}_3\text{N})^2$, PtCl^2 and $\text{PtCl}^2(\text{C}_2\text{H}_5\text{N})^2$, PtCl , analogous to the green salt of Magnus, were discovered in 1850 by Wurtz (iv. 679), who likewise obtained the corresponding chlorides and sulphates. Other ethylamine platinum-compounds have been obtained by Gordon (*Deut. Chem. Ges. Ber.* iii. 174) and by Cleve (*Bull. Soc. Chim.* [2], xvii. 294), who has also studied especially the ammoniacal platinum-compounds containing phenyl.

1. **Platosomethylammonium.** The chloride of this base, $\text{Pt}(\text{CH}_3\text{N})^2\text{Cl}^2$, appears to be obtained by heating the chloride of platosodimethylammonium and dissolving the residue in boiling water (Wurtz).

2. **Platosodimethylammonium.** The *chloroplatinite* of this base, $\text{Pt}[\text{N}^2(\text{CH}_3)^2\text{H}^4]^2\text{Cl}^2 \cdot \text{PtCl}_2$, analogous to the green salt of Magnus, is formed by the action of a strong solution of ethylamine on platinumous chloride, the mixture becoming hot and the chloroplatinite being deposited in the form of a chrome-green powder. On treating it with excess of methylamine in sealed tubes heated in the water-bath, it gives the *chloride*, $\text{Pt}[\text{N}^2(\text{CH}_3)^2\text{H}^4]^2\text{Cl}^2$, which solidifies to a crystalline mass when its solution is evaporated to a syrup. This chloride is less soluble in alcohol than in water. On heating it to 160° and treating the residue with boiling water, a solution is obtained which deposits small shining crystals, probably consisting of the chloride of platosomethylammonium. The green methylic salt treated with nitric acid yields crystals of a nitrate, $(\text{NO}_3)^2[\text{N}^2(\text{CH}_3)^2\text{H}^4]^2 \cdot \text{PtCl}_2$, analogous to Gros' nitrate (p. 990) (Wurtz).

3. **Platosethylammonium,** $\text{Pt} \begin{cases} \text{N}(\text{C}^2\text{H}_5)\text{H}^2- \\ \text{N}(\text{C}^2\text{H}_5)^2\text{H}^2- \end{cases}$. Only one compound of this base is known, viz., the *iodide*, the formation of which will be mentioned further on.

4. **Platosodiethylammoniums,** $\text{Pt} \begin{cases} \text{N}^2\text{H}^4- \\ \text{N}^2(\text{C}^2\text{H}_5)^2\text{H}^4- \end{cases}$; $\text{Pt} \begin{cases} \text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)\text{H}^2 \\ \text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)^2\text{H}^2 \end{cases}$
and $\text{Pt} \begin{cases} \text{N}^2(\text{C}^2\text{H}_5)^2\text{H}^4- \\ \text{N}^2(\text{C}^2\text{H}_5)^2\text{H}^4- \end{cases}$.

The *chloride* of the first of these bases, $\text{Pt} \begin{cases} \text{N}^2\text{H}^4\text{Cl} \\ \text{N}^2(\text{C}^2\text{H}_5)^2\text{H}^4\text{Cl} \end{cases}$, is formed by boiling platosamidiammonium chloride (p. 904) with aqueous ethylamine (Cleve); also by the action of ammonia on the ethylated green salt of Magnus (Gordon). It is not produced by the action of ethylamine on the ordinary green salt. It is a very soluble crystalline mass, the solution of which forms, with platinumous chloride, a compound analogous to the green salt of Magnus (Cleve).

Its isomeride, the chloride, $\text{Pt} \begin{cases} \text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)\text{H}^2\text{Cl} \\ \text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)^2\text{H}^2\text{Cl} \end{cases}$, is formed by the action of ethylamine on platosammonium chloride. It is much less soluble than the preceding modification, and crystallises in beautiful white needles. Its solution forms, with potassium iodide, white nacreous scales, $\text{Pt}[\text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)\text{H}^2]^2\text{I}^2$, which, when boiled, give off ammonia, and are converted into a yellow crystalline powder.

The *chloroplatinite*, $\text{Pt}[\text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)\text{H}^2]^2\text{Cl}^2 \cdot \text{PtCl}_2$, forms green shining sparingly soluble needles. The *sulphate*, $\text{Pt}[\text{NH}^2 \cdot \text{N}(\text{C}^2\text{H}_5)\text{H}^2]^2\text{SO}_4 \cdot 6\text{H}_2\text{O}$, is very soluble, and crystallises in fine colourless prisms which give off their water at 100° (Cleve).

The *chloroplatinite* of the tetraethylated base, $\text{Pt}(\text{NH}^2\text{C}^2\text{H}_5)^4\text{Cl}^2 \cdot \text{PtCl}_2$, or $(\text{C}^2\text{H}_5\text{N})^2\text{PtCl}_2$, is the chamois-coloured salt which Wurtz obtained by the action of ethylamine on platinumous chloride (iv. 679).

5. **Platosodibutylammonium.** The *chloroplatinite*, analogous to the green salt of Magnus, is a green powder formed by the action of butylamine on platinumous chloride. Treated with excess of butylamine, it yields the *chloride* $\text{Pt}[\text{N}^2(\text{C}^4\text{H}_9)^2\text{H}^4]^2\text{Cl}^2$, and with ammonia it yields the *chloride* of *platomonobutylidiammonium*, $\text{Pt}[\text{NH}^2 \cdot \text{N}(\text{C}^4\text{H}_9)\text{H}^2]^2\text{Cl}^2$ (Gordon).

6. **Platosophenylammonium,** $\text{Pt} \begin{cases} \text{N}(\text{C}^6\text{H}_5)\text{H}^2- \\ \text{N}(\text{C}^6\text{H}_5)^2\text{H}^2- \end{cases}$. The *chloroplatinite*, $\text{PtCl}_2 \cdot \text{N}^2(\text{C}^6\text{H}_5)^2\text{H}^4 \cdot \text{PtCl}_2$, analogous to the green salt of Magnus, is easily formed by the action of aniline on platinumous chloride, but is not altered by aniline; it dissolves in water when boiled, and crystallises therefrom in yellow needles which are insoluble in water, alcohol, and ether, and are not altered by hydrochloric or dilute nitric acid (Gordon).

The corresponding *tbluidine salt*, $\text{PtCl}_2 \cdot \text{N}^2(\text{C}^6\text{H}_7)^2\text{H}^4 \cdot \text{PtCl}_2$, is a yellowish powder similar in its properties to the aniline salt. The *xylydine salt*, $\text{PtCl}_2 \cdot \text{N}^2(\text{C}^6\text{H}_7)^2\text{H}^4 \cdot \text{PtCl}_2$, forms whitish needles (Gordon).

a. The *chloride*, $\text{Pt} \begin{cases} \text{N}^2\text{H}^+.\text{Cl}^- \\ \text{N}^2(\text{C}^6\text{H}_5)_2\text{H}^+.\text{Cl}^- \end{cases}$, obtained by heating platosamidiammonium chloride in a sealed tube with excess of aniline mixed with dilute alcohol, is a white crystalline powder which may be freed from coloured products by washing with alcohol. With potassium chloroplatinite it forms a bulky precipitate, $\text{PtCl}_2[\text{N}^2\text{H}^+.\text{N}^2(\text{C}^6\text{H}_5)_2\text{H}^+].\text{PtCl}_2$, analogous to the green salt of Magnus.

Cleve thinks it probable that there exists also a chloride having the composition $\text{Pt} \left\{ \begin{smallmatrix} (\text{NH}^2)^2 \\ (\text{C}^6\text{H}_5\text{N})^2 \end{smallmatrix} \right\} \text{Cl}_2$, as he once obtained a chloride intermediate in composition between this and the one above described.

The *nitrate*, $\text{Pt} \begin{cases} \text{N}^2\text{H}^+.\text{NO}_3^- \\ \text{N}^2(\text{C}^6\text{H}_5)_2\text{H}^+.\text{NO}_3^- \end{cases}$, is prepared by the action of aniline on platosamidiammonium nitrate. It crystallises in very brilliant rhombic scales often having a faint rose tint, due to the presence of small quantities of resinous matter. It dissolves easily in hot water, and the concentrated solution solidifies in crystals on cooling.

The *oxalate*, $\text{Pt} \begin{cases} \text{N}^2\text{H}^+ \\ \text{NH}^2.\text{N}(\text{C}^6\text{H}_5)_2\text{H}^+ \end{cases} \left\{ \text{C}^2\text{O}^4 + \text{H}^2\text{O} \right\}$, obtained by treating the nitrate with ammonium oxalate, is a crystalline powder containing 37.85 p.c. platinum (calc. 37.77).

When the chloride, $\text{Pt} \begin{cases} \text{N}^2\text{H}^+.\text{Cl}^- \\ \text{NH}^2(\text{C}^6\text{H}_5)_2\text{H}^+.\text{Cl}^- \end{cases}$, or the solution formed by boiling platosamidiamine with aniline, water, and a little alcohol, is evaporated on the water-bath, a strongly coloured residue is obtained; and this residue, when washed with alcohol, leaves a whitish crystalline powder, the solution of which in a small quantity of water deposits crystals which, when purified by repeated crystallisation, have the composition $\text{Pt} \left\{ \begin{smallmatrix} (\text{NH}^2)^2 \\ \text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \end{smallmatrix} \right\} \text{Cl}_2$. This chloride is analogous to the chloride of platamonodiammonium, and is formed by the abstraction of 1 mol. aniline from the chloride, $\text{Pt} \left\{ \begin{smallmatrix} (\text{NH}^2)^2 \\ (\text{N}.\text{C}^6\text{H}_5.\text{H}^2)^2 \end{smallmatrix} \right\} \text{Cl}_2$.

When the chloride, $\text{Pt} \left\{ \begin{smallmatrix} (\text{NH}^2)^2 \\ \text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \end{smallmatrix} \right\} \text{Cl}_2$, is treated with potassium iodide, ammonia is given off, and a yellow powder is precipitated having the composition $\text{Pt} \left\{ \begin{smallmatrix} \text{NH}^2 \\ \text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \end{smallmatrix} \right\} \text{I}_2$, analogous to iodide of platosammonium.

The radicle of this iodide may be supposed to be derived from the radicle, $\text{Pt} \left\{ \begin{smallmatrix} \text{NH}^2.\text{NH}^2 \\ \text{N}(\text{C}^6\text{H}_5)_2\text{H}^2.\text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \end{smallmatrix} \right\}$, by abstraction of the two external molecules, NH^2 and $\text{N}(\text{C}^6\text{H}_5)_2\text{H}^2$, just as platosamine is derived from platosodiamine by loss of the two external molecules NH^2 . The isomeric chloride, $\text{Pt} \left\{ \begin{smallmatrix} \text{NH}^2.\text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \\ \text{NH}^2.\text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \end{smallmatrix} \right\}$, to be presently described, behaves differently with potassium iodide, the two external molecules of aniline being given off, and platosammonium iodide, $\text{Pt} \left\{ \begin{smallmatrix} \text{NH}^2.\text{I}^- \\ \text{NH}^2.\text{I}^- \end{smallmatrix} \right\}$, being produced.

The *chloride*, $\text{Pt} \left\{ \begin{smallmatrix} \text{N}^2\text{H}^+ \\ \text{N}(\text{C}^6\text{H}_5)_2\text{H}^2 \end{smallmatrix} \right\} \text{Cl}_2$, unites with platinous chloride, forming the double salt:

analogous to chloroplatinite of platamonodiammonium or to the brown chloride discovered by Peyrone (iv. 674). This double salt forms chamois-coloured scales having a brilliant, almost metallic lustre.

The *sulphate*, $\text{Pt} \left\{ \begin{smallmatrix} (\text{N}^2\text{H}^+)^2 \\ (\text{C}^6\text{H}_5\text{N})^2 \end{smallmatrix} \right\} \text{SO}_4$, is formed by dissolving aniline in a boiling

solution of platosomidiammonium sulphate, and separates on cooling in colourless prismatic crystals, which easily give off part of their aniline.

β. The *chloride*, $\text{Pt}\left\{\begin{smallmatrix} \text{NH}^3\cdot\text{N}(\text{C}^6\text{H}^5)\text{H}^2\cdot\text{Cl} \\ \text{NH}^3\cdot\text{N}(\text{C}^6\text{H}^5)\text{H}^2\cdot\text{Cl} \end{smallmatrix}\right.$, is formed by heating platosammonium chloride, $\text{Pt}(\text{NH}^3)^2\cdot\text{Cl}^2$, with water, aniline, and a little alcohol, and separates from the resulting solution on cooling in thin, nacreous, very light and shining plates. Heated with nitromuriatic acid, it yields yellow crystals having the form of platinammonium chloride. With potassium iodide it forms a yellow precipitate of platosammonium iodide.

The *chloroplatinite*, $\text{PtCl}_2[\text{NH}^3\cdot\text{N}(\text{C}^6\text{H}^5)\text{H}^2]^2\cdot\text{PtCl}_2$, is immediately precipitated as a very sparingly soluble, charmois-coloured, crystalline powder.

The *nitrate*, $\text{Pt}(\text{NH}^3\cdot\text{C}^6\text{H}^5\text{N})^2(\text{NO}^2)^2$, obtained by the action of aniline on platosammonium nitrate, crystallises in thin very brilliant scales, freely soluble in hot, sparingly in cold water.

The *sulphate*, $\text{Pt}(\text{NH}^3\cdot\text{C}^6\text{H}^5\text{N})^2\text{SO}^4$, forms slightly coloured, very thin plates.

POLLEN. The following analysis of this substance has been made by W. v. Schneider (*Ann. Ch. Pharm.* clvii. 235; *Chem. Soc. J.* [2], x. 175).

Water	29.89	p.c.
Ash (chiefly alkaline phosphate)	3.08	"
Albumin and peptones	17.81	"
Sugar	25.12	"
Fat, fat acids, cerotic acid, myricin, oleic acid	8.98	"
Colouring matter	7.56	"
Cell-membrane	7.42	"
Pectin		
	99.86	"

The proportion of wax appears to be very small, whence, as well as from experiments on the consumption of food consumed by bees, in comparison with the wax which they produce, Schneider concludes that bees secrete wax, and that it is not brought into the hive with the pollen which they collect.

POLYCRASE. See TANTALATES.

POTASSIUM. On the solubility of this metal in liquid ammonia, see AMMONIA (p. 60).

On the amalgam of potassium, see MERCURY (p. 786).

Separation from Sodium.—For this purpose T. Schlösing (*Compt. rend.* lxxiii. 1269) recommends the use of ammonium perchlorate, prepared by boiling a concentrated solution of sodium perchlorate with sal-ammoniac, whereby it is obtained in fine crystals. The solution of this salt boiled with nitromuriatic acid is instantly resolved into a mixture of perchloric, nitric, and hydrochloric acids, the perchloric acid decomposing the chlorides and nitrates of the alkalis, and converting them into perchlorates.

To apply this reaction to the separation of potassium and sodium, the solution of the bases, having been concentrated in a tared platinum crucible, is mixed with the perchloric acid solution prepared as above. The whole is then evaporated to dryness, or till white fumes begin to appear; the precipitated potassium perchlorate is washed several times with alcohol, and dissolved in a small quantity of water to separate a little adhering sodium-salt; the solution is evaporated to dryness; the residue again washed with alcohol; and the pure potassium perchlorate dried at 250° and weighed. Test experiments show that this method gives very exact results.

Bromide.—On impurities in the commercial salt, see *Jahresb. f. Chem.* 1870, 300. On the method of testing it, see Falières (*Chem. Centr.* 1872, 425; *Chem. Soc. J.* [2], xi. 191).

Hydrate.—For the preparation of pure potassium hydrate by Wöhler's method (iv. 700), E. Pollacci recommends the use of iron instead of copper, as the potash prepared with copper always contains cupric oxide.

PREHNITE. On the crystalline form of this mineral from the Radanthal, see A. Strong (*Jahresb. f. Mineralogie*, 1870, 314; *Jahresb. f. Chem.* 1870, 1808).

PREHNITIC ACID, $\text{C}^{10}\text{H}^8\text{O}^4$, and **PREHNOMALIC ACID**, $\text{C}^{10}\text{H}^{10}\text{O}^4$. Acids obtained by heating hydromellitic acid with strong sulphuric acid (*1st Suppl.* 811).

PROPANE, C^3H^8 . On dibromo- and dichloropropane or methylbromacetol and methylchloracetol, see PROPYLENE BROMIDES and CHLORIDES (pp. 1016, 1017). On nitropropanes, see PARAFFINS (p. 895).

PROPARGYL COMPOUNDS. Ethyl propargylate or propargylic ether, $C^3H^5OC^2H^5$, was discovered in 1865 by Liebermann, who obtained it by the action of potassium ethylate on bromallylene, and of boiling alcoholic potash on allyl tribromide (1st Suppl. 958). This ether has been further investigated by Liebermann and Kretschner (*Ann. Ch. Pharm.* clviii. 230; *Chem. Soc. J.* [2], ix. 527); and propargylic alcohol, C^3H^5O , has been discovered by L. Henry, who has likewise examined several of its derivatives (*Deut. Chem. Ges. Ber.* v. 274, 449, 569; vi. 728; vii. 20, 761).

Propargyl Alcohol, C^3H^5O or $CH \equiv C-CH^2OH$, is obtained, together with monobromallyl oxide, by the action of aqueous potash on monobromallyl alcohol, $(C^3H^4Br)O$. It is a colourless liquid of peculiar odour, boiling at $114^\circ-116^\circ$; sp. gr. = 0.9628 at 21° . Vapour-density = 1.88 (calc. 1.93). It is easily decomposed by electronegative chlorides, bromides, &c., and unites with Br^2 , HI , and HCl . It precipitates ammoniacal silver and copper solutions, forming the compounds C^3H^4AgO and $C^3H^4(Cu^2)O$. With anhydrous baryta it forms the compound, $(HOC^3H^4)^2Ba.C^3H^4O$, which crystallises in small plates (Henry).

Ethyl Propargylate, C^3H^5O or $CH \equiv C-CH^2(OC^2H^5)$.—Liebermann a. Kretschner find that allyl tribromide is better adapted for the preparation of this ether than trichlorhydrin, as it is more easily decomposed and yields a larger product. At the completion of the reaction, which took five hours in the case of the tribromide of allyl and seven with the trichlorhydrin, the alcohol was distilled off, and the first portions, which contained the ether, collected apart, the receiver being changed as soon as the distillate ceased to give a precipitate with silver nitrate. This last fraction was again rectified in a similar manner. A concentrated solution of silver nitrate was now cautiously added to the alcoholic solution of propargylic ether, and on agitation it became filled with crystalline plates of the silver compound. On adding ammonia to the filtrate, a small additional quantity of silver propargylic ether was generally obtained in the amorphous state. The behaviour of dilute alcoholic solutions of propargylic ether towards silver nitrate was probably the cause why Linnemann (*Ann. Ch. Pharm.* cxxxix. 19) failed to detect it amongst the products of the action of alcoholic potash on trichlorhydrin. In order to prepare the pure ether from the silver compound, it was first treated with ammonia to render it amorphous, and then thoroughly washed. On distilling this compound with dilute sulphuric acid, drying with calcium chloride, and rectifying, the ether was obtained pure. The ether is likewise obtained by the action of boiling alcoholic potash on dichloroglycide, $C^3H^4Cl^2$, and on allylene dibromide, $C^3H^4Br^2$.

According to Henry (*Deut. Chem. Ges. Ber.* v. 274), it is best prepared by heating bromallyl oxide, $C^3H^5OC^2H^4Br$, with an equal weight of potassium hydrate, the yield being nearly equal to the calculated quantity. The greater part separates as an oil on addition of water, and the remainder may be obtained as a silver compound in the manner above described. To remove the last traces of alcohol and water it must be treated with sodium-amalgam.

Ethyl Propargylate is a mobile liquid lighter than water, and boiling at 80° (L. a. K.), at $81^\circ-86^\circ$, and has a specific gravity of 0.83 at 7° (Henry). It has a penetrating odour, is somewhat soluble in water, and in all proportions in alcohol. Bromine combines directly with it without evolution of hydrobromic acid, forming the compound $C^3H^4Br^2O.C^2H^5$, which is heavier than water. This compound is not acted upon by sodium-amalgam in aqueous solution, but in an alcoholic solution the ether is regenerated. It exhibits the reactions assigned by Markownikoff (*Jahresh. f. Chem.* 1865, 492) to the dibromide of allyl ether, and by Tollens (*Ann. Ch. Pharm.* clvi. 167) to the dibromide of allyl alcohol (L. a. K.).

With sodium it forms a white solid compound, containing $C^3H^4Na.OC^2H^5$ (Henry). The crystalline silver compound of propargylic ether has the composition, $2(C^3H^4Ag.OC^2H^5) + AgNO^3$; on treating it with ammonia, silver nitrate separates, and an amorphous silver compound is formed. An alcoholic solution of propargylic ether mixed with an ammoniacal solution of silver chloride yields a white, curdy precipitate, $2(C^3H^4Ag.OC^2H^5) + AgCl$, which gradually gives up silver chloride to ammonia, and is resolved by nitric acid into propargylic ether and silver chloride, whilst silver passes into solution.

A copper compound, $(C^3H^4.OC^2H^5)_2(Cu^2)$, is formed by precipitation with ammoniacal solution of cuprous chloride, as an amorphous, yellow precipitate. Cuprous chloride without ammonia also forms an amorphous precipitate. Respecting the constitution of these metallic derivatives, see *Chem. Soc. J.* [2], ix. 529.

Methyl Propargylate, $C^4H^5OCH^3$, is obtained by heating methylbromallyl ether, $CH^3OC^4H^5Br$, with alcoholic potash; also, together with methylbromallyl ether, by heating the dibromide of methylallyl ether with solid potassium hydrate. It boils at $61^\circ-62^\circ$ (Henry).

Amyl Propargylate, $C^4H^5OC^5H^{11}$, obtained in like manner, is a limpid, nearly scentless liquid boiling at $140^\circ-145^\circ$.

Propargyl Bromides.—The *monobromide*, C^4H^5Br or $CH \equiv C-CH^2Br$, is formed, together with $C^4H^4Br^2$, by treating propargyl alcohol with phosphorous bromide; it is a liquid boiling at $88^\circ-90^\circ$, and having a sp. gr. of 1.59 at 11° , 1.52 at 20° (Henry).

The *tribromide*, $C^4H^3Br^3$, prepared by direct addition of bromine to the monobromide, is a colourless, non-volatile liquid, having a sp. gr. of 2.53 at 10° .

The *pentabromide*, C^4HBr^5 , formed in like manner from the tetrabromide, is a thick non-volatile liquid having a sp. gr. of 3.01 at 10° .

These three bromides may be represented by the following formulæ:

Propargyl Iodide is produced by the action of iodine and red phosphorus on the alcohol; it boils at about 120° , but decomposes at the same time.

Propargyl Acetate is readily obtained by acting on the alcohol with acetyl chloride. It boils at $124^\circ-125^\circ$, has a sp. gr. 1.0031 at 12° and a disagreeable odour.

Propargyl Sulphocyanate, C^4H^5SCN , is easily produced by the action of the bromide on an alcoholic solution of potassium sulphocyanate. It is an oily liquid, smelling like mustard-oil, and decomposed by heat.

Dipropargyl, or **Diallylenyl**, C^4H^4 (L. Henry, *Deut. Chem. Ges. Ber.* vi. 955-963). When diallyl tetrabromide is distilled with a large excess of caustic potash or soda, it loses 2 mols. of hydrobromic acid, and *dibromodiallyl*, $C^4H^4Br^2$, is formed, some of which, by the further loss of hydrobromic acid, is converted into dipropargyl. This isomeride of benzene is a mobile, limpid liquid, having a high refractive index and an odour like that of propargylic ether, but more intense and penetrating. It boils at about 85° , has at 18° the sp. gr. 0.81, and burns with a luminous and smoky flame. It is easily distinguished from benzene by its property of combining with explosive violence with bromine, forming the *tetrabromide*, $C^4H^4Br^4$, a viscid liquid, having a faint smell and bitter taste. Sp. gr. = 2.460 at 19° . When heated it gives off hydrobromic acid, and leaves a carbonaceous residua. It combines in the dark with more bromine, forming probably the *octobromide*, $C^4H^4Br^8$. Dipropargyl gives, with an ammoniacal solution of cuprous chloride, a greenish-yellow precipitate, which, when dried over sulphuric acid, or at $90^\circ-100^\circ$, has the composition $C^4H^4Cu^2 + 2H^2O$. It explodes at about 100° , and when touched with a flame, burns with a scintillating green flame. The silver-compound, $C^4H^4Ag^2 + 2H^2O$, is obtained as an amorphous white precipitate by adding the hydrocarbon to an aqueous solution of silver nitrate; in the light it soon becomes pink, and then black. It explodes below 100° , leaving a residue of carbon and silver.

The constitution of dipropargyl or diallylenyl may be expressed by the formula, $HC \equiv C-CH^2-CH^2-C \equiv CH$, which explains why it forms compounds containing 2 atoms of a metal, while in allylene, $CH \equiv C-CH^2$, only 1 atom of hydrogen can be replaced.

The propargyl-compounds boil $18^\circ-20^\circ$ higher than the corresponding allyl-compounds; dipropargyl ought, therefore, to boil at about $95^\circ-100^\circ$, but it actually boils at 85° . Diallyl makes, however, a similar exception, for while the allyl-compounds boil at the same temperature as the normal propyl-compounds, the hydrocarbon boils at the same temperature as di-isopropyl, or 10° lower than normal dipropyl.

Dipropargyl Tetrabromide, $C^4H^4Br^4$, is a viscid liquid having a faint smell and bitter taste. Sp. gr. = 2.460 at 19° . When heated it gives off hydrobromic acid and leaves a carbonaceous residue.

Octobromide, $C^4H^4Br^8$.—Formed by addition of bromine to the tetrabromide; very little hydrobromic acid is evolved, and in a few minutes the mass becomes solid and crystalline. Thus produced, the octobromide is a granular crystalline powder, but by spontaneous evaporation of its solution in carbon sulphide, distinct rhombohedrons of considerable size may be obtained. It is colourless, strongly refractive, and smells slightly of camphor. It melts at $140^\circ-141^\circ$, and solidifies at 180° . It is not volatile.

PROPIONAMIDE, $C^3H^5O.NH^2$ (F. Sestini, *Cimento*, iv. 21). This compound is best prepared by mixing ethyl propionate with 5-6 times its volume of strong ammonia, leaving the liquid to stand for 3-4 days, and shaking the mixture from time to time. The liquid is first concentrated on the water-bath, and then evaporated over sulphuric acid to the consistence of a syrup, which is exhausted with ether, the solution evaporated, and the residue recrystallised from ether or chloroform.

Propionamide is colourless, readily soluble in cold alcohol and ether, from which it crystallises in radiate crystalline masses, or in prisms grouped in fascicles; from chloroform it crystallises in pearly scales. It melts at 76° - 76° , and solidifies again at 50° ; at a higher temperature it sublimes.

Propionamide Hydrochloride, $(C^3H^5ONH^2)ClH$, is obtained by passing hydrochloric acid gas into an ethereal solution of the amide; the liquid separates into two layers, the lower of which contains the hydrochloride, which is isolated by washing several times with ether and evaporating over sulphuric acid. It crystallises in needles very sparingly soluble in ether, readily soluble in water and alcohol, and having an acid reaction.

Mercury-propionamide, $(C^3H^5O.NH^2)Hg$, is obtained in large colourless quadrate plates by heating an aqueous solution of the amide with mercuric oxide to 50° , and leaving the solution to evaporate slowly; it dissolves sparingly in cold, readily in boiling water.

Propionanilide, $C^3H^5O.NH.C^6H^5$, was obtained by adding drop by drop 3 pts. of propionyl chloride to 10 pts. of well-cooled aniline. It crystallises from water in small micaceous plates which melt at 92° ; at a higher temperature it sublimes partially. By boiling it with acids or alkalis, it is decomposed into propionic acid and aniline.

PROPIONIC ACID, $C^3H^5O^2 = C^3H^5.CO^2OH$. *Formation*.— α . By oxidising allylene with aqueous chromic acid (Berthelot, *Ann. Ch. Phys.* [4], xxiii, 212). β . By the combination of carbon monoxide with potassium ethylate: $CO + C^2H^5OK = C^3H^5.CO^2K$ (Hagemann, *Deut. Chem. Ges. Ber.* iv. 877). γ . By the fermentation of calcium succinate in contact with microzyme chalk (1st Suppl. 614), and a small quantity of meat:

(Béchamp, *Compt. rend.* lxx. 999).

Preparation.—1. *By Oxidation of Normal Propyl Alcohol*. Pierre a. Puchot (*Ann. Chim. Phys.* [4], xxviii. 71) add a mixture of propyl alcohol, water, and sulphuric acid to a solution of potassium dichromate to which sulphuric acid has been added. The reaction being terminated, the mixture yields dilute propionic acid on distillation. In order to obtain the acid in a concentrated form, its potassium salt is treated with sulphuric acid diluted with a small quantity of water, the whole being kept for some time at a temperature of about 80° , when the propionic acid separates as a yellowish liquid which may be decanted from the saline residue. The crude acid thus obtained crystallises on cooling, but after distillation it no longer possesses the property of crystallising at the ordinary temperature, the crystallisation being apparently facilitated by the presence of a small quantity of potassium bisulphate. The acid liquid thus obtained yields, on fractionation, pure propionic acid, $C^3H^5O^2$.

2. *From Lactic Acid by the action of Hydriodic Acid*.—This reaction, discovered by Lautmann (iv. 730), is recommended by A. Fround (*J. pr. Chem.* [2], v. 446) as a convenient mode of preparation. 60 grams of iodine suspended in 140 grams of water are converted into hydriodic acid by means of sulphuric acid, and the hydriodic acid thus obtained is placed in a retort with 60 grams of lactic acid, after which the mixture is distilled until about 100 grams of liquid have passed over. A condensing tube being now adapted to the apparatus, the contents of the retort are digested for about four hours, when the iodine, which by this time has crystallised in the condensing tube, is washed back into the retort with the 100 grams of distillate previously drawn off, and sulphuric acid is passed through the mixture in order to rehydrogenise the free iodine. The deposited sulphur being removed, 100 grams are again distilled off, the contents of the retort are digested for another period of four hours, and his series of operations is repeated six or seven times, the whole of the lactic acid being by this time converted into propionic acid; almost the whole of which is contained in the 100 grams drawn off after the last digestion. This distillate is now mixed with 50 grams of water, and distilled as long as the liquid which passes over produces a perceptible turbidity in a solution of lead propionate. The nearly pure solution of propionic acid thus obtained is neutralised with sodium carbonate, mixed with lead propionate to remove small quantities of iodine, then filtered and evaporated to 2nd Sup.

dryness, and the dry sodium propionate is fused, pulverised, and decomposed by a stream of dry hydrochloric acid gas as recommended by Linnemann (*Ann. Ch. Pharm.* cxlviii. 251). The propionic acid thus liberated is distilled off and freed from hydrochloric acid by passing a stream of dry air through it.

Lactic acid thus treated yields from 61 to 62 p.c. pure propionic acid. No acetic acid is formed in the process, the only secondary products being small quantities of aldehyde and a gas which burns with a bluish flame.

Properties.—Pure propionic acid boils at 139° (Fround), at 140.71° (corrected and reduced to 760 mm. pressure: Linnemann), at 141.5° under the same pressure (Pierre a. Puchot). Sp. gr. = 0.9961 at 19° (Linnemann), 1.0143 at 0° , 0.9607 at 49.6° , and 0.9062 at 99.8° (Pierre a. Puchot). Its odour recalls that of glacial acetic acid and that of butyric acid (Pierre a. Puchot). It mixes in all proportions with water, is optically inactive, and does not solidify at -21° . It is not separated from its aqueous solution by salts, or even by phosphoric acid, and only the concentrated acid is partially dehydrated by calcium chloride, a considerable quantity of hydrochloric acid being at the same time set free and lime dissolved. The dry acid quickly absorbs water from the air (Linnemann, *Ann. Ch. Pharm.* clx. 195).

Propionates.—The neutral ammonium salt, $C^3H^5O^2(NH^4)$, forms long slender prisms, very deliquescent, easily soluble in water, insoluble in ether. When its concentrated solution is left over sulphuric acid, an acid salt, $C^3H^4O^2(NH^4).C^3H^4O^2$, crystallises out in small quadratic plates. On distilling the neutral salt, the acid salt passes over, crystallising in six-sided plates which melt at 45° (Sestini).

The silver salt, $C^3H^4O^2Ag$, crystallises from cold or from hot solution in shining leaflets, or in large broad shining needles, according to the degree of concentration (Linnemann); in masses of fine silky anhydrous needles which execute gyratory movements during the process of solution in water (Pierre a. Puchot). Dissolves in 119 pts. of water at 19° , and is anhydrous at 100° (Linnemann).

The barium salt may be obtained in large crystals by allowing its solution to evaporate spontaneously, or as a granular powder consisting of small crystals by cooling a hot solution. The crystals dried by the heat of the sun contain $(C^3H^4O^2)^2Ba.H^2O$ (Pierre a. Puchot). The salt is anhydrous at 100° , and crystallises by evaporation over sulphuric acid in scales which dissolve in 1.67 pt. water at 17° .

The calcium salt crystallises when its concentrated solution is left over sulphuric acid in transparent laminae which dissolve in 1.87 pt. water at 17° , and when dried at 100° have the composition $(C^3H^4O^2)^2Ca.H^2O$.

The neutral lead salt, $(C^3H^4O^2)^2Pb$, is easily soluble and remains as a gummy mass when its aqueous solution dries up. The very characteristic basic lead salt is always formed when propionic acid or the neutral salt is triturated with excess of litharge and water, and the mixture is dried over the water-bath. If the residue be drenched with cold water, and the filtered solution heated to boiling or evaporated at the boiling heat, the salt separates suddenly and almost completely on stirring, the solution sometimes becoming nearly solid. Dried over sulphuric acid it has the composition $3(C^3H^4O^2)^2Pb + 4PbO$. It separates in needles or as a crystalline powder, which gradually dissolves in 8–10 pts. of water at 14° . This salt affords a ready means of separating propionic acid from formic, acetic, and acrylic acid. The solution mixed with lead oxide and water is evaporated to dryness, the residue is exhausted with cold water, and the basic lead propionate is precipitated by heating the solution. Pseudo-propionic or butyric acid does not exhibit this reaction (Linnemann, *loc. cit.*)

Ethyl Propionate. $C^3H^5O.C^2H^5$, is most easily prepared by distilling a mixture of 24 pts. alcohol of 96 p.c., 18 pts. propionic acid and 4 pts. sulphuric acid (Sestini).

Bromopropionic Acids. *Dibromopropionic acid*, $C^3H^2Br^2O^2$.—Three modifications of this acid are possible, viz.:

and of these, the second and third, distinguished as α and β , are known.

α -Dibromopropionic acid (Friedel a. Machuca, *Compt. rend.* liv. 220; Philipp a. Tollens, *Deut. Chem. Ges. Ber.* vi. 515). This modification is formed by the action of bromine, at 140° , on monobromopropionic acid, $CH^2Br-COOH$, and must therefore be represented by the second or third of the preceding formulae; the second, however, belongs, as will be presently seen, to the β -modification; consequently the acid must be represented by the third.

This acid when pure forms microscopic rectangular plates, melting at 65° (Friedel

a. Machuca), at 61° (Philippi a. Tollens). A mixture of the α - and β -acids remains liquid for a long time, and only after some weeks yields very deliquescent microscopic cubes (P. a. T). The α -acid distils at 227° (at 220° – 221° according to Tollens) with slight decomposition. Silver oxide, in presence of water, transforms it into a non-brominated acid, the calcium salt of which is precipitated by alcohol (Friedel a. Machuca). Treated with zinc and sulphuric acid, it is converted into propionic acid (Philippi a. Tollens).

Barium Dibromopropionate, $(C^2H^3Br^2O^2)^2Ba + 9H^2O$, forms efflorescent needles which give off all their water at 90° . The *calcium salt*, $(C^2H^3Br^2O^2)^2Ca + 2H^2O$, forms silky needles which also give off their water at 90° .

Ethyl Dibromopropionate, $C^2H^3Br^2O^2.C^2H^5$, obtained by the action of hydrochloric acid gas on an alcoholic solution of the acid, forms a liquid of camphorous odour, boiling at 190° – 191° , and having a specific gravity of 1.7536 at 12° (Philippi a. Tollens).

β -Dibromopropionic acid, $CH^2Br-CHBr-COOH$ (Münder a. Tollens, *Deut. Chem. Ges. Ber.* v. 73; *Ann. Ch. Pharm.* clxvii. 222).—This acid is formed by the oxidation of the so-called dibromide of allyl alcohol, $C^3H^4Br^2O$ (p. 48), which is really a glyceric dibromhydrin or a dibromopropyl alcohol. This compound, gently heated with nitric acid of sp. gr. 1.4–1.48, yields the dibrominated acid in crystals, or if stronger nitric acid is used, as an oil which solidifies when dried in the water-bath. The crystals are purified by draining, washing with a little water, pressing between bibulous paper, then melting them, and leaving the fused mass to solidify, again washing, pressing, melting, &c., and repeating this treatment till the acid melts constantly at 62° – 64° .

The formation of β -dibromopropionic acid from allyl alcohol dibromide is represented by the equation:

It is also formed by heating α -monobromacrylic acid with 3 or 4 pts. of hydrobromic acid to 100° :

and, lastly, from α -dibromopropionic acid, by heating with hydrobromic acid to 100° for a week. This remarkable example of a molecular change may be explained by supposing that the α -acid, which at 120° is quickly resolved into hydrobromic acid and α -bromacrylic acid, undergoes the same change slowly at 100° ; thus:

and that the hydrobromic acid then acts on the bromacrylic acid in the manner above mentioned (Philippi a. Tollens, *Ann. Ch. Pharm.* clxxi. 333).

β -Dibromopropionic acid forms rhombic or prismatic crystals belonging to one of the oblique systems. Its melting point is higher than that of the α -acid (61° according to Tollens). It boils with partial decomposition at 220° – 240° . When quite pure it smells like propionic acid; the impure acid has a pungent odour and blisters the skin more strongly than the pure acid. 1 pt. of water at 11° dissolves 19.45 pts. of the acid; calcium chloride and nitric acid separate it from the aqueous solution. 1 pt. of ether at 10° dissolves 3.04 pts. of the acid. Alcohol dissolves it freely. It is not deliquescent.

β -Dibromopropionic acid heated with *alcoholic potash* is converted into bromacrylic acid:

Treated with *sine* and *dilute sulphuric acid*, it gives up 2 at. bromine and is converted into acrylic acid—

(Wagner a. Tollens, *Deut. Chem. Ges. Ber.* vi. 513; *Ann. Ch. Pharm.* clxxi. 340).

When *ammonia* is passed into its aqueous solution, laminar crystals separate which have the composition of ammonium amidobromopropionate, $C^2H^3Br(NH^2)O^2.NH^4$ (Münder a. Tollens).

Dibromopropionates.—The potassium salt, $C^2H^3Br^2O^2K$, forms tabular crystals. The *silver salt*, $C^2H^3Br^2O^2Ag$, is a white, microscopically crystalline precipitate. The *calcium salt*, $(C^2H^3Br^2O^2)^2Ca + 2H^2O$, obtained by neutralisation, crystallises from alcohol in silky needles which effloresce over sulphuric acid. The *strontium salt* crystallises in flexible needles about half an inch long. The *lead salt* is basic and contains 14.33 p.c. lead.

The *methylic ether*, $C^2H^3Br^2O^2.CH^3$, prepared by saturating the solution of the acid

in methyl alcohol with hydrochloric acid, and separated by water, boils at 203° under a pressure of 745 mm. It is colourless, slightly oily, and has a fruity odour. The ethylic ether, $C^2H^5Br^2O^2.C^2H^5$, is colourless, has a somewhat fruity odour when dilute, boils at 211° – 214° under a pressure of 746 mm., and has a density of 1.796 at 0° , 1.777 at 15° . The allylic ether, $C^2H^5Br^2O^2.C^3H^5$, has a disagreeable odour; boils at 215° – 220° under a pressure of 745 mm. Sp. gr. = 1.843 at 0° ; 1.818 at 20° (Mündor a. Tollons).

Chloropropionic Acids. Only one modification of monochloropropionic acid is at present known, viz. the α -acid, $CH^3-CHCl-CO^2H$. The acid produced by the action of phosphorus pentachloride on glyceric acid, and supposed by Wichelhaus to consist of β -chloropropionic acid (1st Suppl. 960), has been shown by Werigo a. Werner (Ann. Ch. Pharm. clxx. 163) to be a chlorinated acrylic acid.

α -Chloropropionic acid boiled with aqueous ammonia yields a large quantity of lactic acid, together with alanine. Alcoholic ammonia acts very slowly on the acid, but when its action is strengthened by the addition of a little concentrated aqueous ammonia, alanine and ethyl-lactic are formed, together with lactic acid. When α -chloropropionic acid is heated with alcohol, α -chloropropionic ether is formed, but no ethyl-lactic acid (W. Heintz, Ann. Ch. Pharm. clvi. 25).

Dichloropropionic acid, $C^2H^2Cl^2O^2$.—Of this acid there are two modifications analogous to those of dibromopropionic acid.

α -Dichloropropionic acid, CH^3-CCl^2-COOH .—The ethylic ether of this acid is obtained by the action of alcohol on the chloride formed by the action of phosphorus pentachloride on pyracemic acid, $CH^3-CO-CO^2H$. This ether, $CH^3-CCl^2-COOC^2H^5$, is a colourless liquid having a pleasant odour of apples, a specific gravity of 1.2493 at 0° , and boiling at 160° . Heated to 130° with water it yields pyracemic acid. Dilute ammonia converts it into dichloropropionamide, $C^2H^2Cl^2O.NH^2$, which is soluble in alcohol, crystallises in large rectangular leaflets melting at 116° , and volatilising before fusion when heated in an open vessel. The ether treated with boiling milk of lime yields an acid which, from the composition of its calcium and barium salts, appears to be carbacetoxylic acid, $C^2H^2O^4$ (Klimenko, Deut. Chem. Ges. Ber. iii. 465; v. 477).

β -Dichloropropionic acid, $CH^3Cl-CHCl-COOH$, is formed by the action of water on the crude product obtained by treating glyceric acid with phosphorus pentachloride. This product contains the chloride, $C^2H^2Cl^2OCl^2$, and when treated with alcohol yields ethyl α -dichloropropionate, which boils at 180° – 190° . This ether dissolves without residue in baryta water even when dilute, and on removing the excess of baryta with carbonic acid and evaporating the solution, either in a vacuum or at a temperature not exceeding 70° , the barium salt, $C^2H^2Cl^2Ba + 11H^2O$, is obtained in mammellated crystals. The solution of this salt is decomposed by alcohol and ether. The dried crystals become heated in contact with water. By treating this salt with silver sulphate, removing the excess of the latter with barium hydrate, and the excess of baryta with carbonic acid, barium chloracrylate, $(C^2H^2ClO^2)^2Ba$, is obtained, its formation taking place as shown by the equation:

The decomposition of this barium salt by sulphuric acid yields chloracrylic acid, which crystallises in small radiate needles, is very volatile at ordinary temperatures, has a strong and peculiar odour, and melts at 65° . These are the properties which Wichelhaus ascribed to his β -chloropropionic acid. This acid, treated with silver oxide, yields silver carbacetoxylic acid, together with metallic silver and silver chloride:

The decomposition of ethyl dichloropropionate may also yield an acid, probably having the composition of monochlorolactic acid (Werigo a. Werner, Ann. Ch. Pharm. clxx. 163).

PROPYL ALCOHOLS and ETHERS. *Normal Propyl Alcohol*, $CH^3-CH^2-CH^2OH$.—The most important results of recent investigations on the formation, preparation, and properties of this alcohol are given in the 1st Suppl. pp. 963, 964. Rossi's method of preparing it from ethyl alcohol is described in detail in the *Gazzetta chimica italiana*, i. 230–239, and a full abstract of the paper is given in the *Journal of the Chemical Society*, [2], ix. 1030.

Linnemann (Ann. Ch. Pharm. clxi. 18) prepares normal propyl alcohol from propionic acid by distilling a mixture of pure and dry propionate and formate of calcium, and reducing the propionic aldehyde thus obtained with sodium amalgam.

Linnemann's method of separating normal propyl alcohol and isobutyl alcohol from a mixture of fermentation alcohols by means of his apparatus for fractional distillation (p. 486) is described in *Ann. Ch. Pharm.* clx. 105; abstr. *Zeitschr. f. Chem.* [2], vii. 675; *Jahresh. f. Chem.* 1871, 397. For Pierre a. Puchot's method of effecting this separation, see *Compt. rend.* lxx. 406; *Jahresh.* 1870, 421.

Allyl alcohol, heated with potassium hydrate, yields a mixture of alcohols, which, when converted into bromides and fractionated, gives a mixture of ethyl and propyl bromides, and the latter, when oxidised, yields propionic acid, with scarcely a trace of carbonic acid, showing that the allyl alcohol has been converted into normal propyl alcohol free from the iso-alcohol (Tollens, *Zeitschr. f. Chem.* [2], vii. 242).

According to Linnemann (*Ann. Chem. Pharm.* clxi. 26) pure normal propyl alcohol, prepared by distilling propyl benzoate with aqueous potash, boils at 97.41° and has a sp. gr. of 0.8066 at 15° .

Respecting the conversion of normal propyl alcohol into isopropyl alcohol, see below.

Normal Propyl Bromide, $\text{CH}^3\text{--CH}^2\text{--CH}^2\text{Br}$, boils, according to Pierre a. Puchot (*J. Pharm.* [4], xiii. 9) at 72° , and has a sp. gr. of 1.3197 at 0° , 1.301 at 15° , 1.2599 at 54.2° , the coefficient of expansion increasing with the temperature. According to Linnemann (*loc. cit.*) it boils at 70.82° , and has a sp. gr. of 1.3507 at 16° .

Monobromopropyl Bromide, $\text{C}^3\text{H}^6\text{Br}^2 = \text{CH}^3\text{Br--CH}^2\text{--CH}^2\text{Br}$, is formed by heating 5 grams of propyl bromide and 6.5 grams of bromine for four hours to $130^{\circ}\text{--}140^{\circ}$. It boils at $141^{\circ}\text{--}161^{\circ}$, and has a density of 1.9463 at 17° . With acetic acid and zinc it yields propylene. Heated with 6 vols. water to 200° for six hours, it is decomposed, yielding hydrobromic acid and acetone. From these reactions it appears to be identical with the propylene dibromide formed by the action of bromine on isopropyl bromide (Linnemann, *loc. cit.*)

Propyl Chloride, $\text{C}^3\text{H}^7\text{Cl}$, is a limpid colourless liquid having a sweet though slightly ulliaceous odour. Boils at 46.5° . Sp. gr. 0.9156 at 0° , 0.8918 at 19.75° , 0.8671 at 39° (Pierre a. Puchot, *Ann. Chim. Phys.* [4], xx. 234; *Jahresh. f. Chem.* 1871, 372; *Chem. Soc. J.* [2], ix. 808). Linnemann, by heating propyl iodide with iodine monochloride, obtained propyl chloride boiling at 46.36° , and having a sp. gr. of 0.9160 at 18° ; by heating the iodide with mercuric chloride to $130^{\circ}\text{--}140^{\circ}$, propyl chloride was obtained boiling at 46.44° , and having a sp. gr. of 0.8959 at 19° .

Propyl Iodide, $\text{C}^3\text{H}^7\text{I}$, obtained by treating the pure alcohol with anhydrous hydriodic acid, is a mobile liquid smelling like ethyl iodide, and boiling at 192.2° . Sp. gr. at $16^{\circ} = 1.7610$. It is not changed by heating with fuming hydriodic acid to 150° , but when it is heated with 6 vols. of water to 100° for 24 hours, about 36 p.c. is converted into propyl alcohol and hydrogen iodide. By the action of silver oxide or mercuric oxide on a solution of the iodide in glacial acetic acid at 100° , a small quantity of propylene is formed, besides propyl oxide, propyl acetate, and propyl alcohol. Not a trace of an isopropyl compound was formed in any of these decompositions (Linnemann).

Propyl Oxide, $(\text{C}^3\text{H}^7)^2\text{O}$, smells like ethyl oxide and boils at $82^{\circ}\text{--}86^{\circ}$ (Linnemann).

Propyl Acetate is a mobile liquid, smelling like acetic ether, and at the same time like fruit. Boiling point, 101.98° ; sp. gr. at $15^{\circ} = 0.8992$.

Propyl Propionate has a faint but pleasant odour, like that of pears. Boiling point 122.44° ; sp. gr. at $13^{\circ} = 0.8885$.

Propyl Butyrate smells like other butyric ether. Boiling point, 143.42° ; sp. gr. at $15^{\circ} = 0.8789$.

Propyl Benzoate is a thick, colourless, refractive liquid, possessing hardly any smell at the common temperature, but its vapour is irritating and produces coughing. Boiling point, 229.47° ; sp. gr. at $16^{\circ} = 1.0316$ (Linnemann).

Boropropyllic Ether.—When a current of pure boron chloride is passed very slowly into anhydrous propyl alcohol at 0° , the gas is absorbed, and two layers of liquid are formed. The upper layer, after purification, yields *boropropyllic ether* (or *propoxyl boride*), $\text{B}(\text{OC}^3\text{H}^7)_2$, which is a colourless, mobile liquid, having a density of 0.807 at 16° , boiling at $172^{\circ}\text{--}175^{\circ}$. When applied to the tongue it causes a burning sensation and leaves a slightly bitter after-taste. Alcohol, ether, and water dissolve it readily. The aqueous solution decomposes, boric acid being deposited. Propoxyl boride burns with a green-edged flame, dense fumes of boric acid being at the same time evolved (Cahours, *Compt. rend.* lxxvi. 1383).

Propyl Allophanate, $\text{C}^3\text{H}^{10}\text{N}^2\text{O}^3 = \text{C}^3\text{H}^8\text{N}^2\text{O}^2.\text{C}^3\text{H}^7$, is produced, together with propyl urethane, by the action of propyl alcohol on urea. It forms pearly laminae slightly soluble in cold water, very soluble in hot water and in alcohol (Cahours).

Propyl Carbamate or *Propyl-urethane*, $C^3H^7O = CO.NH^2.OC^3H^7$, formed at the same time, according to the equation :

may be separated from the excess of urea by digesting with ether, evaporating the ethereal solution to dryness, dissolving in a little water, and evaporating the aqueous solution. It forms long, colourless, shining prisms, readily soluble in water or alcohol. It melts at $51^{\circ}-53^{\circ}$, and boils at $104^{\circ}-106^{\circ}$ (Cahours).

Tripropyl Biuret, $CON^2(C^3H^7)^2.CONH^2$.—When a mixture of potassium propyl-sulphate and potassium cyanate is distilled, propylene is given off, and a yellowish solid distillate is obtained which, after crystallisation from alcohol, is found to have the composition of this substance (Roemer).

Propyl Sulphydrate or *Propyl Mercaptan*, $C^3H^7S = CH^2-CH^2-CH^2SH$, is obtained by digesting normal propyl bromide with an alcoholic solution of potassium sulphhydrate, distilling the product, and adding water to the distillate. Under these circumstances the mercaptan is precipitated as a colourless mobile liquid, having the characteristic odour of mercaptans. It boils at $67^{\circ}-68^{\circ}$, is not quite insoluble in water, and unites with freshly precipitated mercuric oxide, forming the mercaptide $(C^3H^7S)^2Hg$, which crystallises in shining leaflets melting at 68° (H. Roemer, *Deut. Chem. Ges. Ber.* vi. 785).

Propyl-disulphocarbonic Acid.—The potassium salt of this acid is obtained in shining yellow needles by adding carbon disulphide to a solution of potassium hydrate in normal propyl alcohol, and crystallising the yellowish mass which is deposited. The addition of an acid to the potassium salt causes the separation of free propyl disulphocarbonic acid in the form of an oil which soon decomposes (Roemer).

lxxvi. 133).—This compound is readily obtained by heating potassium monosulphide with iodide or chloride of propyl in alcoholic solution, the action being completed at the temperature of the water-bath in sealed tubes. Most of the alcohol is evaporated off, and the residue treated with water, which leaves undissolved a fetid oil lighter than water, boiling at $130^{\circ}-135^{\circ}$ after dessication with anhydrous calcium chloride, and of specific gravity 0.814 at 17° .

When treated with propyl iodide and a little water in sealed tubes, this sulphide gives rise to a sulphine-iodide, $S(C^3H^7)^2I$, and this iodide, treated successively with silver oxide, hydrochloric acid and platinum chloride, yields a platino-chloride containing $[S(C^3H^7)^2Cl]^2PtCl^4$.

Similarly, propyl iodide combines with the sulphides of ethyl and methyl, giving rise to the compounds $S(C^2H^5)^2I$ and $S(C^2H^5)(CH^3)^2I$, which form the platino-chlorides—

and the iodides of ethyl and methyl combine with propyl sulphide to form analogous compounds.

METALLIC COMPOUNDS OF PROPYL (Cahours, *Compt. rend.* lxxvi. 133, 1383).

Mercury-propyl.—When propyl iodide is treated by Frankland & Duppa's process (action of sodium amalgam in presence of acetic ether), mercury-propyl is obtained, forming a liquid insoluble in water, slightly soluble in alcohol, and readily soluble in ether, boiling at $189^{\circ}-191^{\circ}$, and having the specific gravity 2.124 at 16° . Iodine and bromine combine with this substance with great energy, producing crystalline compounds crystallisable from alcohol.

Zinc-propyl is formed by acting on mercury-propyl with zinc at $100^{\circ}-120^{\circ}$, or by treating propyl iodide with an alloy of zinc and sodium.

Aluminium-propyl is produced by acting on mercury-propyl with thin aluminium foil at 120° in sealed tubes; it distils in hydrogen at $240^{\circ}-245^{\circ}$, and is decomposed by water with production of gelatinous alumina.

Glucinum-propyl is formed by acting on mercury-propyl with thin plates of glucinum in a sealed tube at $130^{\circ}-135^{\circ}$, and distilling the product in an atmosphere of carbonic anhydride. After rectification it forms a colourless liquid, boiling at $244^{\circ}-246^{\circ}$, and in contact with the air, giving off dense fumes which sometimes take fire. At -17° it is a thick oil. Water decomposes it with violence, forming large quantities of gas and glucinum hydrate.

Stannopropyl Compounds.—On treating propyl iodide with tin-foil or with an alloy of tin and sodium, *stannotripropyl iodide*, $Sn(C^3H^7)^3I$, is formed, eight or ten hours

heating in the water-bath in sealed tubes being sufficient. When the contents of the tube are treated with ether, and the ethereal solution of the tin-compound is distilled, a liquid boiling at 265° – 272° passes over, which by rectification easily yields pure stannotripropyl iodide, boiling at 269° – 270° . On heating this substance with strong aqueous potash, *stannotripropyl hydrate*, $\text{Sn}(\text{C}^3\text{H}^7)_3\text{OH}$, is obtained as a heavy oil, which concretes on standing to a magnificently crystallised mass made up of inter-laced prisms having an alkaline reaction; this substance is dehydrated by distillation with caustic baryta, forming *stannotripropyl oxide*—

which is reconverted into the hydrate by addition of water; sulphuric acid forms with this oxide a compound but little soluble in water, but crystallisable in fine prisms from alcohol; similarly acetic, formic, butyric acids, &c., form well-crystallised compounds, which much resemble the corresponding substances in the stannotriethyl and stannotrimethyl series.

Stannotripropyl Cyanide is obtained as a crystalline sublimate by heating in a tube sealed at one end a mixture of stannotripropyl iodide and silver cyanide.

Isopropyl Alcohol, $\text{CH}^3\text{—CHOH—CH}^3$. This alcohol may be formed by heating normal propylamine nitrite, prepared by distilling the hydrochloride with silver nitrite:

The crude isopropyl alcohol thus obtained contains nitroso-dipropylamine, formed by the reaction:

This base remains behind when the alcohol, after dehydration with potash, is distilled at the heat of the water-bath.

Isopropyl alcohol thus prepared boils at $82\text{--}85^{\circ}$ (corrected and reduced to 760 mm.) and has a density of 0.7876 at 16° .

Isopropyl Iodide, prepared from it by the action of hydriodic acid, boils at $89\text{--}90^{\circ}$ (corrected and reduced). The iodide, bromide, and chloride of isopropyl are easily decomposed by water, and when heated to 100° for 48 hours, dissolve in 12.8 and 6 pts. of water, respectively (Linnemann, *Ann. Ch. Pharm.* clxi. 26; *Chem. Soc. J.* [2], x. 236).

Action of the Copper-zinc Couple on the Iodides of Propyl.—Isopropyl iodide is rapidly decomposed by zinc alone at its boiling point (89°), whereas the normal iodide is decomposed very slowly by zinc, even at its higher boiling point (101°). The iso-compound is decomposed by the copper-zinc couple at about 50° , the normal compound at about 80° . In this decomposition half of the iso-compound is split up into permanent gases, whereas little, if any, of the normal compound is decomposed in this manner. The resulting liquid in the one case (zinc-isopropyl?) is scarcely volatile; that in the other case (zinc-propyl) rises easily in vapour, notwithstanding its high boiling point. The first is decomposed at about 132° , giving mainly gases and metallic zinc; the second distils over unchanged at a higher temperature.

The reaction between the propyl iodide and water, or alcohol, with the couple, takes place much more rapidly in the case of the iso-compound than in that of the normal compound, an olefine making its appearance during the decomposition of the first, but not of the second.

On comparing these results with those obtained with the ethyl and amyl compounds, it is evident that it is the normal, and not the isopropyl iodide that is acted upon in an analogous manner. The main difference perhaps is that there seems to be no crystalline propyl-iodide of zinc, but that the reaction is mainly, if not wholly—

(Gladstone & Tribe, *Chem. Soc. J.* [2], xi. 960).

Isopropyl Chloride submitted to the action of chlorine in sunshine in a flask cooled by ice yields two compounds, having the composition $\text{C}^3\text{H}^7\text{Cl}^2$, viz. dichloropropane, methyl-dichloroethane or methyl-chloroacetol, $\text{CH}^3\text{—Cl}^2\text{—CH}^3$, and propylene dichloride, $\text{CH}^3\text{—CHCl—CH}^2\text{Cl}$, the former being the more abundant. The presence

of a trace of iodine facilitates the formation of propylene dichloride at the expense of the dichloropropane, and by the action of iodine chloride in sealed tubes, propylene dichloride only is obtained. Isopropyl bromide is converted by bromine into propylene dibromide (Friedel a. Silva, *Compt. rend.* lxxiii. 1379).

Isopropyl Benzoate, formed by the action of a dilute ethereal solution of the iodide on silver benzoate, remains, on evaporating its ethereal solution, as a faintly yellow oily syrup, insoluble in water, and splitting up when heated into benzoic acid and propylene (Linnemann).

Isopropyl Formate, $C^3H^7.CHO^2$, prepared by the action of isopropyl iodide on cupric acetate at 120° , boils at $65^\circ-67^\circ$ (bar. at 44.7 mm.) The *cyanate*, $C^3H^7.CNO$, obtained by treating the iodide with silver cyanate, boils at 74° . *Mono-isopropyl lactate*, $C^3H^7.C^3H^5(OH)O^2$, obtained by heating lactic acid with isopropyl alcohol, boils at $166^\circ-168^\circ$. *Di-isopropyl lactate*, $(C^3H^7)^2.C^3H^5O^2$, formed by the action of isopropyl iodide on the sodium derivative of the preceding ether, boils at a slightly higher temperature (Silva, *Bull. Soc. Chim.* [2], xvii. 97).

Isopropyl Sulphhydrate, *Thioisopropyl Alcohol*, or *Isopropyl Mercaptan*, is obtained by mixing isopropyl iodide with an alcoholic solution of potassium sulphhydrate, leaving the mixture to stand for some time in the cold, then slowly heating it on the water-bath till about one-half has distilled over. If the mixture be heated at once, but little mercaptan is obtained, but in place of it a less volatile oil, which, even under the most favourable conditions, constitutes at least a fourth part of the crude product. The above distillate is mixed with water, the oil which separates is dried and rectified, and the portion boiling between $56^\circ-65^\circ$ is collected apart. By fractional distillation, the main bulk of the mercaptan is obtained, boiling at $57^\circ-60^\circ$, but it is impossible to obtain a purer product, since on distillation it is partially decomposed, with evolution of sulphuretted hydrogen.

Thioisopropyl alcohol is violently acted upon by concentrated nitric acid, and converted into isopropyl-sulphonic acid, $C^3H^7.SO^2OH$. The potassium salt of this acid is obtained by the action of isopropyl iodide on potassium sulphite. It yields a series of well-crystallised salts (Claus a. Keerl, *Deut. Chem. Ges. Ber.* vi. 659).

PROPYLAMINES. On the conversion of normal propylamine into isopropyl alcohol, see p. 1015.

Tetrapropylammonium Iodide and *Tetrapropylammonium Hydroxide*.—By digesting normal propyl iodide with alcoholic ammonia, again treating the mixed bases so formed with propyl iodide, distilling off the excess of propyl iodide, and adding soda to a solution of the product, *tetrapropylammonium iodide* is separated in the solid state. It crystallises in beautiful white prisms. By digesting this compound with silver chloride the iodine is replaced by chlorine, and on adding platinum chloride, a red crystalline salt is deposited, having the composition $[(C^3H^7)^4NCl]PtCl^4$. When *tetrapropylammonium iodide* is treated with silver hydrate, the hydroxide, $(C^3H^7)^4N.OH$, is liberated. It forms a deliquescent mass which absorbs carbonic acid from the air. It is not decomposed at 100° , but at a higher temperature it is decomposed into propylene, tripropylamine, and ammonia.

The platinum salt of tripropylamine crystallises in brick-red leaflets, less soluble in water than in alcohol or ether (H. Roemer, *Deut. Chem. Ges. Ber.* vi. 784).

PROPYLENE or **PROPENE**, $C^3H^6=CH^2-CH=CH^2$. To obtain this hydrocarbon by Berthelot's method of reducing allyl iodide with hydrochloric acid and zinc, Tollens a. Henninger (*Ann. Ch. Pharm.* clvi. 156) gradually pour concentrated hydrochloric acid upon granulated zinc immersed in alcohol of 90 p.c. The gas, which is evolved without application of heat, contains only one-eighth of its volume of hydrogen.

When propylene bromide is treated with sodium amalgam and water, zinc and hydrochloric acid, or zinc and acetic acid, propylene is regenerated in all cases, but when acetic acid is used, the product obtained is sensibly less than with the other reducing agents; there is, moreover, considerable elevation of temperature. On submitting the product to fractional distillation, a viscous mixture of hydrocarbons remains, which is readily attacked by bromine, yielding a mixture of bromides. By fractional distillation this viscous mixture of hydrocarbons yields a mobile liquid boiling between 70° and 80° , as well as one boiling between 330° and 340° . The latter is colourless, slightly viscous, somewhat lighter than water, and appears to consist of hexpropylene, $(C^3H^6)^2$; the liquid boiling between 70° and 80° is probably dipropylene, $(C^3H^6)^2$ (Frunier, *Compt. rend.* lxxvi. 98).

Propylene Bromides, $C^3H^5Br^2$. Three compounds are known, having the composition, viz.:

1. *Ordinary Propylene bromide* is obtained:—1. By the direct union of bromine with propylene. 2. Either pure or mixed with methylbromacetol, by the action of hydrobromic acid saturated at 10° on monobromopropylene. 3. Together with another isomeride boiling at 163° , by the action of hydrobromic acid saturated at 10° on allyl bromide (Géromont, *Bull. Soc. Chim.* [2], xvi. 113; Reboul, *ibid.* xvii. 360). 4. By the action of bromine on isopropyl bromide (Linnemann).

Propylene bromide is a liquid having a sweet taste and smell, a sp. gr. of 1.974, and boiling at 143° . With alcoholic potash it forms bromopropylene boiling at 51° , and the latter treated with sodium alcohol at the temperature of the water-bath yields allylene. (Sawitsch, *Compt. rend.* lii. 399). By silver acetate propylene bromide is converted into propylene diacetate (Wurtz, *Ann. Chim. Phys.* [3], lv. 438), and by silver benzoate into non-crystallisable dibenzoate (Friedel a. Silva, *Compt. rend.* lxxiii. 1370).

A mixture of the bromides of propylene and ethylene in equivalent proportions, such as is obtained when amyl alcohol is decomposed at a red heat and the resulting hydrocarbons are absorbed by bromine, boils constantly at 134° , and cannot be resolved into the constituent bromides by fractional distillation. The separation may, however, be effected by treating the mixture with potassium acetate in alcoholic solution, the ethylene bromide being thereby converted into diacetate, while the propylene bromide remains nearly unaltered (Bauer, *Ann. Ch. Pharm. Suppl.* i. 250).

2. *Normal Propylene bromide*, $CH^2Br-CHBr-CH^2Br$; *Trimethylene bromide* (Géromont); *Hydrobromide of Allyl bromide* (Reboul).—This is the compound which Géromont and Reboul obtained, simultaneously with the preceding, by the action of hydrobromic acid on allyl bromide. It boils at $162^\circ-164^\circ$, and has a specific gravity of 2.017 at 0° , 1.93 at 19° . It is decomposed by alcoholic potash at 100° , yielding allyl bromide and allyl-ethyl oxide.

3. *Methyl-bromacetol*, $CH^3-CBr^2-CH^3$, *Dichloropropane*, *Dibromethyl-methane*. Formed by the action of pentabromide or trichlorodibromide of phosphorus on acetone, and by direct addition of hydrobromic acid to allylene or its monohydrobromide. It boils at $115^\circ-118^\circ$ (Linnemann), at 116° (Friedel a. Ladenburg); at 114° (Reboul).

Bromopropylenes. 1. *Monobromopropylene*.—Of this compound there appear to be two modifications, isomeric with allyl bromide, $CH^2=CH-CH^2Br$.

1. Allylene treated with hydrobromic acid yields dibromopropane, or methyl bromacetol, and a bromopropylene having the constitution $CH^2=CH-CBr=CH^2$. This latter is also formed by the action of alcoholic soda at 100° on dibromopropane, and by treating the hydrobromide of bromopropylene with alcoholic potash. It boils at $48^\circ-49^\circ$ under a pressure of 710 mm. and has a specific gravity of 1.39 at 9° . It unites with 2 at. bromine, forming a tribromide which boils at 190° , and is isomeric with bromopropylene bromide boiling at $194^\circ-196^\circ$, and with glyceric tribromhydrin boiling at 217° . Monobromopropylene heated to 100° with hydrobromic acid saturated at 10° is reconverted into dibromopropane (Reboul, *Bull. Soc. Chim.* [2], xvi. 60; xvii. 351).

2. Propylene bromide treated with alcoholic potash yields a monobromopropylene which, according to Linnemann (*Ann. Ch. Pharm.* clxi. 43), has a density of 1.4110 at 15° and boils at 57.6° (corr. and reduced); according to Reboul (*Bull. Soc. Chim.* [2], xiv. 60) it boils at 54° , and has a constitution represented by the formula $CH^3-CH=CHBr$.

This bromopropylene heated to 100° with mercuric acetate in presence of glacial acetic acid is converted into acetone; by hypochlorous acid and mercuric oxide it is converted into monochloracetone; these reactions do not agree very well with Reboul's formula. The bromopropylene heated to 100° with hydrobromic acid saturated at $+10^\circ$ forms propylene bromide; but with the same acid diluted with $\frac{1}{2}$ of its volume of water, it forms, according to a former statement by Reboul (*loc. cit.*), a mixture of methyl-bromacetol and propylene bromide. Bromopropylene unites slowly at common temperatures with concentrated hydriodic acid, forming monobromopropylene hydriodide, $C^3H^5Br.HI$. This compound boils with slight decomposition at 148° , and has a density of 2.20 at 11° . It is identical with allylene hydrobromide, $C^3H^5.HBr.HI$, and when treated with alcoholic potash yields allylene hydrobromide (b. p. $48^\circ-49^\circ$), together with a small quantity of allylene hydriodide.

With *hydrochloric acid* of 22° Baumé, bromopropylene yields propylene chlorobromide, C^3H^5ClBr , boiling at 112°–113°, and having a density of 1.62 at 16° (Reboul). Bromopropylene, heated to 100° in a sealed tube with *sodium ethylate*, yields allylene (Sawitsch, *Compt. rend.* lii. 399).

Dibromopropylene, Dibromhydroglycide, or Epidibromhydrin, $C^3H^4Br_2$.—This body, of which there are probably two modifications, is formed by the action of potash, or of sodium, on tribromhydrin:

According to Reboul it boils at 151°–152°; according to Henry at about 10° lower; this difference points to the existence of two modifications. It unites with *bromine*, forming $C^3H^4Br_4$, and is decomposed by *alcoholic ammonia*, forming dibromallylamine, $NH(C^3H^4Br)_2$ (ii. 899). With *silver nitrate* in alcoholic solution it forms bromallyl nitrate, $C^3H^4Br(NO_2)$, an oily liquid insoluble in water. With *silver acetate* it forms bromallyl acetate, $C^3H^4Br.C^2H^3O_2$, a colourless mobile fragrant liquid, insoluble in water, having a density of 1.57 at 12°, boiling at 163°–164°, forming addition-products with chlorine and bromine.

Dibromopropylene, treated with dry *potash* at common temperatures, or distilled with fragments of soda, is easily transformed into bromallyl alcohol, C^3H^4BrOH :

This alcohol, like its acetate, is a colourless, mobile, fragrant liquid, insoluble or slightly soluble in water, having a density of 1.6 at 15°, boiling at 155°. It is attacked by phosphorus pentachloride, giving off hydrogen chloride, and forming monobromallyl chloride, $C^3H^4BrCl = CH^2=CBBr-CH^2Cl$. This compound is also a chlorobromopropylene. It boils at 120°, and has a density of 1.63 at 11°. It is probably identical with Reboul's chlorobromhydroglycide or epichlorobromhydrin, formed by heating chlorodibromhydrin with potash (ii. 899).

Monobromallyl alcohol, treated with alcoholic potash, yields propargylic alcohol (p. 1007).

Dibromopropylene, treated with *potassium sulphocyanate* in alcoholic solution, yields bromallyl sulphocyanate, $C^3H^4Br.CNS$, which is a colourless pungent liquid boiling at about 200° (L. Henry, *Deut. Chem. Ges. Ber.* v. 186, 452).

Propylene Chlorides, $C^3H^4Cl^2$. Two bodies having this composition are known, viz.:

Propylene Chloride is formed: 1. By the direct action of chlorine on propylene. 2. By passing chlorine into propylene chloriodide under water till all the chlorine is dissolved (this is an easy mode of preparation) (Friedel a. Silva, *Compt. rend.* lxxvi. 1596). 3. By the action of chlorine on propane (Schorlemmer, *1st Suppl.* 967). 4. Together with methyl-chloracetol, by the action of chlorine in sunshine on isopropyl chloride. 5. By the action of iodine chloride on isopropyl chloride; in this case it is the only compound of formula $C^3H^4Cl^2$ produced (Friedel a. Silva, *Compt. rend.* lxxiii. 1380).

Propylene chloride is a liquid boiling at 98°, and having a sp. gr. of 1.584 at 0°, 1.165 at 14° (Friedel a. Silva). Treated with alcoholic potash it yields a chloropropylene identical with that which is formed from methyl-chloracetol (Friedel, *Ann. Chim. Phys.* [4], xvi. 349).

Methyl-chloracetol, $CH^3-CH^2-CH^3$. *Dichloropropane. Dichlorethyl-methane*.—This compound, formed by the action of phosphorus pentachloride on acetone, is a liquid boiling between 25° and 35° (*1st Suppl.* 825). Treated with chlorine or with iodine chloride, it yields a trichlorinated body, $CH^3-CCl^2-CH^2Cl$, boiling at 125°, and having a density of 1.350 at 0°, 1.318 at 25°. This trichloride is identical with that which is formed by the addition of chlorine to chloropropylene, and with one of those formed by the chlorination of propylene chloride under the influence of chlorine. It is easily decomposed by water at 175°–180°, yielding a non-volatile product which resinifies when evaporated by heat, reduces ammoniacal silver nitrate, and remains after evaporation in a dry vacuum as a yellow amorphous mass, emitting an odour of caramel when burnt. The residue, insoluble in water, contains two dichloropropylenes.

boiling respectively at 75° and 94° ; they are formed from methyl-chloroacetol by loss of HCl (Friedel a. Silva, *Compt. rend.* lxxiv. 806).

Methyl-chloroacetol, heated to 100° for several days with silver benzoate in presence of ether, yields crystals of methyl-benzoacetol, $(\text{CH}^3)_2\text{C}=\text{C}(\text{C}^6\text{H}_5\text{O}_2)^2$, identical with those which Oppenheim obtained in like manner from methyl-chloriodoacetol (1st Suppl. 826).

Dichloromethyl-chloroacetol, $\text{C}^2\text{H}^4\text{Cl}^4$, also called *dichloroacetone chloride*, is formed by the action of phosphorus pentachloride on dichloroacetone. Its properties and reactions have been already described (1st Suppl. 27, 28). Its reduction to allylene by the action of sodium indicates that it is the true tetrachloride of allylene, $\text{CH}^3-\text{CCl}^2-\text{CHCl}^2$.

Methyl-chloriodoacetol, $\text{CH}^3-\text{CH}^2-\text{CH}^2$, is also described in the 1st Suppl. (p. 826).

Propylene Chlorobromide, $\text{C}^3\text{H}^4\text{BrCl} = \text{CH}^3-\text{CHCl}-\text{CH}^2\text{Br}$, is obtained by heating propylene bromide with mercuric chloride. It is a liquid boiling at 120° , having a sp. gr. of 1.585 at 0° , 1.475 at 18° . Vapour-density (obs.) = 5.52; (calc.) 5.45. Alcoholic potash converts it into monochloropropylene, boiling at $25^{\circ}-30^{\circ}$ (Friedel a. Silva, *Bull. Soc. Chim.* [2], xvii. 532).

Propylene Chloriodide, $\text{C}^3\text{H}^4\text{Cl}^2 = \text{CH}^3-\text{CHCl}-\text{CH}^2\text{I}$. Maxwell Simpson obtained this compound, isomeric with methyl-chloriodoacetol, by the action of iodine chloride in aqueous solution on propylene; he describes it as a liquid which cannot be distilled (*ibid.* [2], v. 500). According to Friedel a. Silva (*ibid.* xvii. 535), it is very easily obtained by passing propylene into a bulb-apparatus containing a solution of iodine monochloride, and may be distilled without decomposition. It boils at 149° under ordinary pressure, at $40^{\circ}-43^{\circ}$ under a pressure of 10-12 mm. Sp. gr. = 1.933 at 0° , 1.889 at 25° . It is limpid, and resembles propylene bromide. It is easily converted into propylene chloride, by heating it to 100° with mercuric chloride, or by exposing it to the action of chlorine under water (Friedel a. Silva). Heated with hydriodic acid it is converted into isopropyl iodide (Sorokin, *Deut. Chem. Ges. Ber.* iii. 616).

Chloropropylenes. **Monochloropropylene**, $\text{C}^3\text{H}^4\text{Cl} = \text{CH}^3-\text{CCl}=\text{CH}^2$, isomeric with allyl chloride, $\text{CH}^2=\text{CH}-\text{CH}^2\text{Cl}$, is obtained by the action of potash on propylene chloride, and on methyl-chloroacetol; also by the action of silver acetate or of ammonia on methyl-chloroacetol. It boils at 25.5° , and has a sp. gr. of 0.9307 at 0° . Vapour-density = 2.83 (obs.) = 2.65 (calc.). Sulphuric acid converts it into acetone (Oppenheim, *Compt. rend.* lxx. 354). It unites with 2 at. bromine, forming the compound $\text{C}^3\text{H}^4\text{ClBr}_2 = \text{CH}^3-\text{CClBr}-\text{CH}^2\text{Br}$, which boils at $170^{\circ}-175^{\circ}$, and has a sp. gr. of 2.064 at 0° . This chlorobromide, treated with alcoholic potash or silver acetate, gives up HBr, and is converted into a chlorobromopropylene, $\text{C}^3\text{H}^4\text{ClBr} = \text{CH}^3-\text{CCl}=\text{CHBr}$, or $\text{CH}^3-\text{CCl}=\text{CH}^2\text{Br}$, which boils between 100° and 110° (Friedel, *Ann. Chim. Phys.* [4], xvi. 343). It is isomeric with Reboul's chlorbrom-hydroglycide, $\text{CH}^2-\text{CBr}=\text{CH}^2\text{Cl}$.

Chloropropylene, heated to 120° with alcoholic potash, is converted into allylene (Friedel, *Compt. rend.* lix. 294). It combines with hydrogen iodide at 100° , forming methyl-chloriodoacetol. Chlorine in sunshine converts it into $\text{C}^3\text{H}^4\text{Cl}^2$, isomeric with glyceric chlorhydrin, boiling at 127° , and identical with dichloromethyl-chloroacetol.

Dichloropropylenes, $\text{C}^3\text{H}^4\text{Cl}^2$ (Friedel a. Silva, *Compt. rend.* lxxiii. 957; lxxiv. 806; lxxv. 81).—Three of these compounds are known, namely:

The first two are formed simultaneously when monochloropropylene is treated with chlorine in the shade. The first boils at 75° , the second at 94° ; the latter, which forms by far the larger part of the product, is identical with the dichloropropylene which is produced, together with dichlorohydroglycide (boiling at 108°), by the action of dry potash on trichlorhydrin. The third compound is dichlorohydroglycide.

1. The dichloropropylene melting at 75° is likewise obtained by the action of water at 180° and of alcoholic potash on dichloromethylchloroacetol. It unites with bromine less readily than the following compound, forming a bromide which boils with partial decomposition at 190° .

2. The dichloropropylene boiling at 94° , $\text{CH}^3-\text{CCl}=\text{CH}^2\text{Cl}$, is formed in both the reactions above mentioned, especially in the first; also in that of dry potash on tri-

chlorhydrin. It combines energetically with bromine, forming a very stable bromide which boils at 205°; easily also with hydrochloric acid when heated with a solution saturated at 6°, forming dichloromethylchloracetol. Sulphuric acid converts it into monochloracetone (Henry, *Deut. Chem. Ges. Ber.* v. 86). With alcoholic potash it yields a chlorinated ether, $\text{CH}^2=\text{CCl}-\text{CH}^2.\text{OC}^2\text{H}^5$, boiling at 110°, having a density of 1.011 at 0°, and 0.995 at 21°. This ether takes up 2 at. bromine, forming a chlorobrominated ether, $\text{CH}^2\text{Br}-\text{CClBr}-\text{CH}^2.\text{OC}^2\text{H}^5$.

3. *Dichlorhydroglycide* or *Epidichlorhydrin*, $\text{CHCl}=\text{CH}-\text{CH}^2\text{Cl}$ (b.p. 106°), is formed, together with the second isomeride, by the action of potash on trichlorhydrin:

It is obtained pure by the action of phosphoric anhydride on dichlorhydrin (b.p. 174°):

Allyl-alcohol dichloride, $\text{CH}^2\text{Cl}-\text{CHCl}-\text{CH}^2\text{OH}$, which is isomeric with dichlorhydrin, does not yield it. It does not unite with hydrochloric acid. With alcoholic potash it likewise yields a chlorinated ether, $\text{CHCl}=\text{CH}-\text{CH}^2.\text{OC}^2\text{H}^5$, boiling at 120°-125°, and having a density of 1.021 at 0° and 0.991 at 25°. This ether appears to be identical with that which Henry obtained by addition of Cl^2 to ethyl-allyl oxide, and treatment of the product with alcoholic potash. It takes up 2 at. bromine, forming a product which distills at about 220°, but decomposes at the same time, with separation of easily alterable, uncrystalline, crystalline laminae (Friedel u. Silva).

Isomeric with the three dichloropropylones is the chloride obtained from acrolein by the action of phosphorus pentachloride (i. 147). Its constitution, which results directly from that of acrolein, is represented by the formula, $\text{CH}^2=\text{CH}-\text{CHCl}^2$.

Tetrachloroglycide, $\text{C}^2\text{H}^2\text{Cl}^4$, formed by fixation of chlorine on dichlorhydroglycide, is a colourless liquid having a strong ethereal odour, density = 1.406 at 17°, and boiling at 164°. The isomeric compound, dichloracetone dichloride, formed by the action of phosphorus pentachloride on acetone (1st Suppl. 27), boils at 153°.

Sodium acts strongly on tetrachloroglycide, but if this compound be diluted with hydrocarbons and slowly heated, gas is evolved with regularity, consisting of allylene mixed with propylene.

Tetrachloroglycide treated with alcoholic potash yields a chloride, $\text{C}^2\text{H}^2\text{Cl}^2$, boiling at 142° and having a density of 1.414 at 20°.

Alcoholic ammonia transforms tetrachloroglycide into tetrachlorodiallylamine, $\text{NH}(\text{C}^2\text{H}^2\text{Cl}^2)^2$, which is a colourless alkaline liquid, decomposing at 200°, slightly soluble in water, soluble in acids. Its *hydrochloride* forms white needles soluble in water and in alcohol. The *platinochloride*, $2[\text{NH}(\text{C}^2\text{H}^2\text{Cl}^2)^2.\text{HCl}].\text{PtCl}_4$, crystallises in small crimson prisms, soluble in water and in alcohol, less soluble in ether. The *sulphate* is uncrystallisable. The *dioxalate*, $\text{NH}(\text{C}^2\text{H}^2\text{Cl}^2)^2.\text{C}^2\text{H}^2\text{O}^4$, is very soluble in water and crystallises from alcohol in leaflets (Pfeffer u. Fittig, *Ann. Ch. Pharm.* cxxxv. 357).

Chlorobromoglycide or *Epichlorobromhydrin*, $\text{C}^2\text{H}^2\text{ClBr} = \text{CHCl}=\text{CH}-\text{CH}^2\text{Br}$ or $\text{CHBr}-\text{CH}=\text{CH}^2\text{Cl}$, obtained by the action of dry potash on chlorodibromhydrin, has been already described (i. 899). It boils at 126°-127°, and is isomeric with the chlorobromopropylene, $\text{CH}^2=\text{CCl}=\text{CHBr}$ or $\text{CH}^2=\text{CCl}-\text{CH}^2\text{Br}$, obtained by abstraction of HBr from the chlorobromide of propylene (p. 1019).

Trichloropropylene, $\text{C}^2\text{H}^2\text{Cl}^3$.—Obtained, together with dichlorallylene, by decomposing crotonic chloral with caustic soda. It is a liquid of agreeable odour, boiling between 138° and 140°. It has not, however, been obtained pure. It is not attacked by soda-ley in the cold, but alcoholic potash quickly removes from it a molecule of hydrogen chloride, converting it into dichlorallylene. Trichloropropylene takes up 2 at. bromine (Pinner, *Deut. Chem. Ges. Ber.* v. 206).

Propylene Glycols, Propylene Hydroxides, or Propylene Alcohols, $\text{C}^2\text{H}^4(\text{OH})^2$. Two of these compounds are known, viz.:—1. *Ordinary Propylene glycol* or *Propyl-glycol*, $\text{CH}^2-\text{CHOH}-\text{CH}^2\text{OH}$, analogous to ordinary propylene bromide, and obtained by saponifying the corresponding propylene diacetate with potash (Wurtz). This compound has been already described as *TRIPYLENE GLYCOL* (v. 882).

2. *Normal Propylene Glycol*, $\text{CH}^2\text{OH}-\text{CH}^2-\text{CH}^2\text{OH}$. *Trimethylene glycol*.—This compound, probably analogous to malonic acid, $\text{GO}^2\text{H}-\text{CH}^2-\text{CO}^2\text{H}$, is prepared by treating normal propylene bromide (p. 1017) with silver acetate in presence of

acetic acid, and saponifying the resulting diacetate (b. p. 203°–205°) with baryta. It is a thick saccharine liquid boiling between 206° and 218° (Géromont, *Deut. Chem. Ges. Ber.* iv. 548; Reboul, *Bull. Soc. Chim.* [2], xvii. 350).

Propylene Chlorhydrin or **Monochlorhydrin of Propyl-glycol** (ordinary), $C^3H^5 \begin{Bmatrix} OH \\ Cl \end{Bmatrix} = CH^2-CH.OH-CH^2Cl$. Produced by the action of gaseous hydrogen chloride on propylene glycol; the mixture at first becomes hot, but must be warmed on the water-bath towards the end to complete the reaction. The product is distilled up to 135°, and then treated with sodium carbonate to neutralise the hydrochloric acid. Two layers of liquid are thus formed, the upper of which consists of the chlorhydrin. The greater part distils over at 127°. The same compound is obtained by the action of hypochlorous acid on propylene:

Propylenic chlorhydrin boils at 127°. Sp. gr. = 1.302 at 0°. Vapour-density = 3.38 (obs.) = 3.26 (calc.) It is neutral, has an ethereal odour and a saccharine but pungent taste. It dissolves in water, also in alcohol, ether, and a mixture of the two, but is insoluble in solutions of sodium chloride and calcium chloride. Sodium carbonate does not act on it at ordinary temperatures, but when heated converts it into propylene oxide. Aqueous potash immediately decomposes it into potassium chloride and propylene oxide (Oser, *Bull. Soc. Chim.* 1860, 235).

Propylenic chlorhydrin, heated with *potassium cyanide* in sealed tubes, is converted into the corresponding cyanhydrin, $C^3H^5(OH)CN$, which when boiled with *potash* yields β -oxybutyric acid, $CH^2-CHOH-CH^2-CO^2H$ (1st *Suppl.* 891).

Phosphoric anhydride converts propylenic chlorhydrin into a mixture of allyl chloride and monochloropropylene:

Propylenic chlorhydrin unites with *bromine* in sunshine, without evolution of hydrobromic acid (Henry a. Henninger, *Deut. Chem. Ges. Ber.* iv. 602).

Propylene Nitrate, or **Propylenic Dinitrin**, $C^3H^5(NO^2)^2 = CH^2-CH(NO^2)-CH(NO^2)$. Fuming nitric acid acts violently on nitric acid, rendering it necessary to cool the mixture during the reaction. On subsequently adding water, propylene nitrate is deposited as a colourless oil (Henry, *loc. cit.*)

Propylene Oxide, $C^3H^5O = CH^2 - \begin{array}{c} \diagup \diagdown \\ O \end{array} - CH^2$. This compound is obtained, by adding aqueous potash to crude propylene chlorhydrin, as a very volatile liquid which may be purified by fractional distillation. It must be dried with fused potash, as calcium chloride retains it. It is a neutral liquid, having an ethereal odour, and a harsh pungent taste. Boils at 35°. Sp. gr. = 0.859 at 0°. Vapour-density = 2.0 (obs. and calc.) It is miscible in all proportions with water, alcohol and ether, insoluble in solution of calcium or magnesium chloride. Heated for a few seconds in a sealed tube with magnesium chloride, it forms a copious precipitate of magnesium hydrate (Oser, *Bull. Soc. Chim.* 1860, 237).

Epichlorhydrin, C^3H^5ClO , is the oxide of chloropropylene.

Propylene Benzoate, $C^3H^5(C^7H^5O^2)^2$. A. Mayer described this compound as forming fine crystals isomorphous with ethylene benzoate (1st *Suppl.* 300); but according to Friedel a. Silva (*Compt. rend.* lxxiii. 1379), it is a viscid uncrystallisable liquid, boiling at 240°, under a pressure 12–14 mm.

The *acetate*, *cyanide*, *iodide*, *sulphide* and *sulphocarbonate* of propylene are described, in vol. v. p. 893, as **TRITYLENIC ETHERS**.

PROPYLENE-DIAMINE, $C^3H^5(NH^2)^2$, (Hofmann, *Deut. Chem. Ges. Ber.* vi. 308). This base is obtained by heating propylene bromide with ammonia in a closed vessel. On heating the product with potash in the water-bath, to expel ammonia and alcohol, and then raising the temperature, propylene-diamine passes over at about 120°. At higher temperatures, 200° and above, viscous bases distil over, probably consisting of secondary and tertiary diamines. To dehydrate the propylene-diamine, it is heated with sodium, then distilled in a stream of hydrogen, and again heated with sodium.

Anhydrous propylene-diamine is a colourless, transparent, mobile liquid, boiling at 119°–120°, and having a density of 0.878 at 15°. It is so hygroscopic, that a glass rod moistened with it fumes in the air; it also rapidly attracts carbon dioxide. The *hydrate*, $2C^3H^5.NH^2.H^2O$, boils at the same temperature as the anhydrous base. The

hydrochloride, $C^3H^4(NH^2)^2 \cdot 2HCl$, forms long white needles, very hygroscopic, and very freely soluble in water, less soluble in alcohol.

The *platino-chloride*, formed only in concentrated solution, crystallises in beautiful four-sided plates. The *hydrobromide* and *hydriodide* greatly resemble the hydrochloride; has not been obtained in crystals.

PROPYL-ETHYL KETONE, $C^3H^{12}O = C^3H^7 \cdot CO \cdot C^2H^5$. *Ethyl-butyryl*.—This compound, isomeric with Frankland & Duppa's isobutyl-methyl-acetone and with methyl-valeryl, was discovered by Friedel amongst the products of the distillation of calcium butyrate (i. 608), and is produced synthetically by the action of zinc-ethyl on butyryl chloride (Butlerow, *Bull. Soc. Chim.* [2], v. 17):

It is a liquid boiling at 122° – 125° , having a density of 0.818 at 17.5° . It does not unite with sodium bisulphite at ordinary temperatures, but on heating the mixture, and then leaving it to cool, crystalline scales are deposited which ultimately dissolve. In the dry state the combination is stable, but water quickly resolves it into propyl-ethyl ketone and sodium bisulphite.

The ketone oxidised by potassium dichromate and dilute sulphuric acid is converted into propionic acid: $C^3H^7 \cdot CO \cdot C^2H^5 + O^2 = 2(C^2H^5O \cdot OH)$, (Popoff, *Ann. Ch. Pharm.* clxi. 285).

PROPYL-METHYL CARBINOL, $C^3H^7 \cdot CHOH \cdot CH^3$ (see AMYL ALCOHOLS, 1st Suppl. 111).

PROPYL-METHYL KETONE, $C^3H^{10}O = C^3H^7 \cdot CO \cdot CH^3$. This ketone was also first noticed by Friedel, amongst the distillation-products of calcium butyrate; Butlerow obtained it synthetically by the action of zinc-methyl on butyryl chloride; and it has been especially studied by Friedel (*Ann. Chim. Phys.* [4], xvi. 366), and by Grimm (*Ann. Ch. Pharm.* clvii. 249), both of whom obtained it by the distillation of a mixture of acetate and butyrate of calcium. Schorlemmer (p. 63) has obtained it by oxidation of the secondary alcohol derived from normal pentane. It is a colourless liquid, boiling at 111° (Friedel), at 102° – 105° (Schorlemmer), at 99° – 101° (Grimm), at 95° (Butlerow), and having a density of 0.837 at 0° , 0.8078 at 15° (Grimm). It is only slightly soluble in water, but mixes freely with alcohol and ether. It unites with alkaline bisulphites, forming crystallisable compounds which are decomposed by water. The sodium salt contains $C^3H^7NaSO^3 + 1\frac{1}{2}H^2O$.

The ketone treated with phosphorus pentachloride reacts like ketones in general, exchanging O for Cl^2 , and forming methyl-chlorobutyrol, or dichloropentane, $C^3H^7Cl^2$, which boils at about 140° , and is resolved by distillation into hydrogen chloride and chloramylene or chloropentane, C^3H^5Cl , boiling at about 95° . This last body, heated to 140° with alcoholic potash, again gives up HCl , and is converted into valerylene, C^4H^6 , a homologue of acetylene, which distils towards 50° (v. 981), (Friedel).

Propyl-methyl ketone combines directly with nascent hydrogen, forming propyl-methyl carbinol, $C^3H^{10}O = C^3H^7 \cdot CHOH \cdot CH^3$ (1st Suppl. 111), (Grimm), and a pinacone, $C^6H^{12}O^2$, which boils at 225° – 230° , and when recently distilled, forms a colourless liquid, but solidifies after some time to a white crystalline mass, melting at a gentle heat (Friedel).

Propyl-methyl ketone yields, by oxidation with chromic acid mixture, acetic and propionic acids, with a small quantity of carbonic acid (Schorlemmer).

Propyl-methyl ketone is identical with the ethyl-acetone of Frankland & Duppa, and isomeric with propiono, isopropyl-methyl ketone (1st Suppl. 768), and valeral.

PROPYL-PHYCITE, $C^3H^4(HO)^4$? (1st Suppl. 963). Experiments apparently confirming the existence of this supposed compound have been made by J. G. Wolff, in Carius's laboratory (*Ann. Ch. Pharm.* cl. 28); but Carius himself has thrown doubt upon their accuracy (*Bull. Soc. Chim.* [2], xiv. 240), and further experiments by Claus (*Deut. Chem. Ges. Ber.* iii. 525) tend to corroborate his former conclusion that the supposed propyl-phycite does not exist.

PROTEIDS. Several attempts to get an insight into the molecular construction of these bodies have lately been made, but with only very partial success. The most important are, perhaps, Nasse's experiments, from which he has drawn some conclusions as to the state in which their nitrogen exists in them, (*Studien über die Eiweisskörper*; *Pflüger's Archiv.* vi. p. 589); he treated various proteids in the dried and powdered state with caustic baryta for forty or fifty hours, and systematically

examined the products of decomposition; the main result at which he arrives is that, in the same proteid, nitrogen exists in several very different states of combination, part being held very firmly, and part being easily turned out. From the comparison of the combinations in which the loosely-held nitrogen appears, with the results of the action of caustic baryta on nitrogenous bodies whose molecular constitution is known, such as amine-acids, acid amides, nitrides, leucine, &c., he considers it extremely probable that a definite quantity of the loosely-combined nitrogen of proteids is combined as in amides; another part as the nitrogen in creatine or the more loosely-held portion of the nitrogen of uric acid, and most of the remainder as in the acid amides and the difficultly expulsi- ble nitrogen of creatine or sarcosine.

Béchamp (*Compt. rend.* 1870) oxidised proteids with potassic permanganate, and found that urea was produced, together with many other bodies; as almost all proteids taken into the body leave it in the form of urea, this result promised to be of importance, but very great doubt has been thrown upon its accuracy (Loew, *J. pr. Chem.* 1870). Treated with powerful oxidising bodies, proteids yield various acids of the fatty series, and their aldehydes, benzoic acid, ammonia, and various compound ammonias.

The complete separation of proteids from animal fluids has been much facilitated by a new method of precipitation devised by Brücke (*Wien. Akad. Ber.* 1871); this consists in acidulating the liquid with hydrochloric acid, and then adding to it a solution of potassio-mercuric iodide, made by saturating with mercuric iodide a boiling solution of potassic iodide.

The changes which proteids undergo in the animal body from the time they enter it from the alimentary canal until they leave it as urea, or uric acid, are still almost totally unknown. It has already been pointed out (GLYCOGEN, p. 567) that there is considerable reason to believe that they are partly broken up in the liver, bile-acids and urea being produced from them, together with glycogen; while in the muscles (MUSCULAR TISSUE, p. 830) it would appear that much less breaking up of proteids occurs than was formerly supposed (see also UREA). In the alimentary canal the gastric juice splits them up into peptones, parapeptones and other bodies, and one of the pancreatic ferments also converts them into peptones, but afterwards goes further, and breaks the peptones up into tyrosine and leucine (see DIGESTION, p. 430). Peptones do not appear to exist either in the blood or in chyle, and so must be converted into some other form of proteid immediately upon entering either of these fluids.

H. N. M.

PROTocatechuic Acid, $C^H^O^4$. This acid has been shown by Barth (*Deut. Chem. Ges. Ber.* iv. 633), and Romsen (*Zeitschr. f. Chem.* vii. 81, 199, 294), to be the 1 : 3 : 4 form of dioxibenzoic acid, C^H^3 $\begin{matrix} OH \\ OH \\ COOH \end{matrix}$ (p. 431).

It is formed from piperonylic acid (methylene-protocatechuic acid) by heating the latter to 150° with dilute hydrochloric acid, the only products of the reaction being protocatechuic acid and free carbon:

With pure water at 210° the same decomposition takes place, but the protocatechuic acid is resolved by the high temperature into CO^2 and pyrocatechin (Fittig & Romsen, *Ann. Ch. Pharm.* clix. 129). Conversely piperonylic acid may be formed synthetically by heating protocatechuic acid with methylene iodide and potassium hydrate (p. 983).

Preparation from Kino.—Stenhouse finds that East Indian kino is the best source of protocatechuic acid, and the one which yields it most readily. One part of the kino in fine powder is gradually added to three parts of fused sodic hydrate, stirring the mixture constantly during the introduction of the kino, the most convenient method being to sift the fine powder over the surface of the hydrate, which is kept fused at a gentle heat. When the mixture has acquired a bright orange-brown colour, it is poured out on a stone or an iron plate, and allowed to cool. The cake is then broken up and dissolved in about 20 pts. of hot water, to which dilute sulphuric acid is added from time to time, so as to render the solution slightly acid. The dark brown solution is then allowed to stand for 24 hours, when it deposits a large quantity of sodium sulphate in the crystalline state; the mother-liquors which contain the protocatechuic acid, after being filtered to remove a small quantity of tarry matter, are agitated with ether. The ethereal solution is then separated, and the ether recovered by distillation in the water-bath; the dark-coloured syrupy residue on standing deposits the protocatechuic acid in the crystalline state. The mother-liquors may be

readily separated from the crystals by means of the vacuum pump, and the acid is then easily purified by one or two crystallisations from a small quantity of hot water, with the addition of some freshly precipitated lead sulphide, which removes the brown colouring matter (*Chem. Soc. J.* [2], xiii. 8).

Action of Bromine.—Barth has shown that protocatechuic acid treated with excess of bromine in the cold is converted into bromopyrocatechuic acid, $C^6H^3BrO^4$, by simple substitution of Br for H (1st *Suppl.* 976). If, however, this monobrominated acid, or pyrocatechuic acid itself, be heated in sealed tubes with excess of bromine to 100° , a totally different reaction takes place, resulting in the formation of tetrabromopyrocatechin (Stenhouse, *loc. cit.*):

On Dimethyl- and Diethyl-protocatechuic acids, see pp. 431, 432 of this volume.

homologous with piperonylic acid (methylene-catechuic acid) is formed similarly to the latter (p. 983), by mixing 3.5 grams of protocatechuic acid, in a tube, with 10 grams of ethylene bromide and 4½ grams of solid potassium hydrate, then sealing the tube, and shaking it, with occasional immersion in warm water, till the free protocatechuic acid and the potash have united into a brown viscid mass; this treatment is absolutely necessary to the success of the experiment. The tube is then heated in the water-bath for five or six hours and shaken from time to time; the mass afterwards exhausted with hot alcohol; the solution gently warmed with potassium hydrate, and the residue mixed with water and dilute hydrochloric acid, and well shaken with ether. On evaporating the ether, the ethylene-protocatechuic acid remains as a dark-coloured mass, which may be easily purified by recrystallisation from water, with addition of animal charcoal.

Ethylene-protocatechuic acid crystallises from water in colourless indistinct crystals, from alcohol in druses of short shining prisms. It closely resembles piperonylic acid, and, like the latter, is nearly insoluble in water, but in boiling water it dissolves much more readily than piperonylic acid. It melts at 133° , and at a higher temperature sublimates without decomposition in shining prisms. Its calcium salt crystallises well, and is somewhat sparingly soluble. The barium salt crystallises in large, finely developed transparent crystals, which apparently belong to the orthorhombic system. The solutions of these salts give a yellow precipitate with ferric chloride (Fittig a. Remsen, *Zeitschr. f. Chem.* vii. 289).

PROTocatechuic ALDEHYDE, $C^6H^4O^3 = C^6H^3 \begin{matrix} \diagup (OH)^2 \diagdown \\ \diagdown CHO \diagup \end{matrix}$. This compound is formed, with separation of carbon, by heating piperonal (methylene-protocatechuic aldehyde) with dilute hydrochloric acid, just as protocatechuic acid is formed from piperonylic acid; also, together with hydrochloric acid and carbon dioxide, by heating dichloropiperonal with water (Fittig a. Remsen, *loc. cit.*) For its properties and reactions, see 1st *Suppl.* 976.

PROTOPINE, $C^8H^9NO^3$ (Hesse, *Zeitschr. f. Chem.* vii. 653). An alkaloid occurring in very small quantity in opium, and obtained from the mother-liquors remaining after the separation of morphine by the Robertson-Gregory process. The method of separating it from the other bases present in these mother-liquors is given in the article *Opium Bases* (pp. 876-877). The protopine is finally precipitated from the solution of its hydrochloride by ammonia, and dissolved in acetic acid; the solution is treated with a small quantity of charcoal, and, after addition of alcohol, precipitated by ammonia.

Protopine is a white crystalline powder, insoluble in water, slightly soluble at the boiling heat in alcohol, benzene and acetone, almost insoluble in the last two liquids at common temperatures. Chloroform dissolves it also, but moderately, though more readily than other solvents. Ether dissolves it very sparingly; when recently precipitated it dissolves in ether somewhat more freely, but separates partially after a short time in warts or spherical groups of prisms, which are very characteristic of protopine, as no other alkaloid of opium forms crystals of similar character. Cryptopine under the same circumstances separates in rhombohedrons.

Protopine is slightly soluble in caustic potash and soda; it does not colour ferric chloride. With strong nitric acid it forms a colourless solution, which turns yellow on

the slightest warming. Pure concentrated nitric acid forms at 20° a yellow solution which after some time turns red, and finally bluish-red; acid containing ferric oxide forms immediately a dark violet solution; at 150° both solutions change to dirty brownish-green.

Protopine melts at 262° with partial decomposition; it has an alkaline reaction, and neutralises acids; the salts have a bitter taste, and do not gelatinise.

The *hydrochloride* forms rather large, apparently rhombic prisms, very sparingly soluble in hot and in cold water. The *platinochloride*, $2(C^{20}H^{23}NO^3.HCl).PtCl_4 + 2H_2O$, is a yellow crystalline precipitate, slightly soluble in cold water. The *bitartrate* forms small prisms, somewhat sparingly soluble in cold water. The *bioxalate* forms warty groups of prisms which dissolve easily in boiling water, with difficulty in cold water, though more readily than the corresponding cryptopine salt. The *sulphate* forms small needles.

PSEUDO-ACONITINE, syn. with NAFELLINE; also called ACRACONITINE. See ACONITE ALKALOIDS (p. 23).

PSEUDOCORALLIN. This name is applied by H. Fresenius to Wanklyn's Caro's rosolic acid (1st Suppl. 999; also p. 391 of this volume).

PSEUDOHEPTYL ALCOHOL. *Dipropyl Carbinol*.—Obtained, together with butyrene-pinacone, by the action of sodium on dipropyl ketone (butyrene) mixed with a little water:

It boils at 149°–150° (Schorlemmer's normal heptyl alcohol from petroleum boils at 175.5°–177.5°), dissolves sparingly in water, easily in alcohol in all proportions. By oxidation with potassium dichromate and sulphuric acid, it is converted into butyrene. With iodine and phosphorus, it yields the corresponding *iodide*, $C^8H^{17}.CHI.C^8H^{17}$, which has a density of 1.2 at 20°, and boils with partial decomposition at 180° (C. M. Kurz, *Ann. Ch. Pharm.* clxi. 205).

PSEUDOISOPYRINE. See ISOPTRYNE (p. 707).

PSEUDOMORPHINE, $C^{17}H^{19}NO^4$. Hesse (*Zeitschr. f. Chem.* [2], vii. 643). Many kinds of opium appear to contain little or none of this base. For the method of separating it from the other opium-bases see 1st Suppl. 976. On mixing the hot dilute aqueous solution of its hydrochloride with potassium-sodic tartrate, a hydrate of pseudomorphine separates in white shining scales, having nearly the composition $C^{17}H^{19}NO^4 + 4H_2O$; the same solution precipitated with ammonia, gives scales whose composition is nearly $C^{17}H^{19}NO^4 + 1\frac{1}{2}H_2O$. Hesse supposes that there are two hydrates containing respectively 1 and 4 mols. of water, and that the precipitates above mentioned are mixtures of the two.

Pseudomorphine dissolves in strong *sulphuric acid*, without colour at first, but the solution soon turns olive-green, and if slightly heated, quickly assumes a dingy green colour. Water added to a solution recently prepared in the cold throws down crystalline pseudomorphine sulphate. With *nitric acid* of sp. gr. 1.06°, pseudomorphine forms in the first instance a nitrate of pseudomorphine; but if the nitric acid is in excess, a nitrate of nitropseudomorphine, separating in small yellow crystals, which, however, very quickly decompose. Pseudomorphine is not altered by sulphurous acid, by hydrogen sulphide, or by zinc, either in acid or in alkaline solution.

Acid Tartrate of Pseudomorphine, $C^{17}H^{19}NO^4.C^4H^6O^6 + 6H_2O$, may be prepared by adding tartaric acid to the solution of the acetate; it crystallises in small prisms, which dissolve in 429 pts. of water at 18°, and are moderately soluble in boiling water. The *hydrobromide*, formed on adding potassium bromide to a solution of the acetate, crystallises in small prisms, slightly soluble in water. The *hydriodide*, $C^{17}H^{19}NO^4.HI + H_2O$, is formed by adding potassium iodide to a solution of the hydrochloride, slightly acidulated with acetic acid; it crystallises in small prisms, soluble in 793 pts. of water at 18°. The *chromate*, $2C^{17}H^{19}NO^4.Cr^2H^2O^7 + 4H_2O$, separates on adding potassium dichromate to the aqueous solution of the hydrochloride, in small yellow prisms, which appear brownish-yellow in the mass, coffee-brown after drying at 80°. It gives off two-thirds of its water of crystallisation over sulphuric acid, the remainder at 80°; takes fire when heated a little above 100°. Dissolves in 990 pts. water at 18°; insoluble in alcohol.

PSEUDOPURPUREIN. See PURPUREIN.

PSEUDOTOLUIC ACID. See TOLUIC ACID.

PSEUDOTOLUIDINE. See TOLUIDINE.

2nd Sup.

3 U.

PUCHERITE. This mineral is a bismuth vanadate found in a mine at Schneeberg in Saxony, in small crystals of the rhombic system, mostly recognisable only with the lens. The following combinations have been observed:—

1. $\infty P . oP$, and $oP . \infty P$.
2. $\infty P . \tilde{P}\infty$.
3. $\infty P . oP . m\tilde{P}n$.
4. $oP . \infty P . \tilde{P}\infty . m\tilde{P}n$, and $\infty P . \tilde{P}\infty . m\tilde{P}n . oP$.

A pyramid of the principal series mP , and the pinacoids $\infty \tilde{P}\infty$, and $\infty \tilde{P}\infty$, have also been observed, the two latter, however, only in very narrow strips. Twins likewise occur.

Cleavage perfect parallel to the base. Lustre vitreous to adamantine. Colour reddish-brown to brownish-red; occasionally also limpid yellowish-brown, hyacinth-red, and dark yellowish-brown. Streak-powder, ochre-yellow. Opaque to translucent. Hardness near that of fluorspar. Sp. gr. (allowing for adhering quartz) = 6.249.

The mineral decrepitates violently before the blowpipe; melts on charcoal, and gives a yellow deposit of bismuth oxide, and when fused on charcoal with sodium carbonate, yields metallic bismuth. With borax and phosphorus salt, it gives the reactions of vanadium.

It dissolves easily in hydrochloric acid, with evolution of chlorine, forming a deep red liquid, which becomes green on standing, or immediately on dilution with water; when poured into a large quantity of water, it yields a yellowish-white precipitate of basic bismuth chloride containing vanadic acid; with ammonia it yields a yellowish to greyish-white precipitate of vanadiferous bismuth hydrate.

Analysis gave 73.16 p.c. Bi^2O_3 , 22.19 V^2O_5 , 3.66 As^2O_3 , 1.34 P^2O_5 (= 100.35), agreeing with the formula of a bismuth monovanadate, $Bi^2O_3.V^2O_5$, in which the vanadium is partly replaced by arsenic and phosphorus (Frenzel, *J. pr. Chem.* [2], iv. 227, 361; *Jahrb. f. Mineralogie*, 1872, 514). On the crystalline form, see also Welsky (*ibid.* 1873, 183).

PURPLE OF CASSIUS. See GOLD (p. 576).

PURPURATES and ISOPURPURATES (E. Kopp, *Deut. Chem. Ges. Ber.* 7, 644). The best yield of potassium isopurpurate is obtained by mixing intimately finely powdered picric acid with twice its weight of potassium cyanide and a little water. After half an hour more water is added, and the mixture is heated to 40° – 45° , and then allowed to cool; the crystals separating out are pressed and purified according to Hlasiwetz's method (iii. 434).

In dyeing with isopurpurates the same mordants are used as in dyeing with murexid, the best being mercury and lead salts. Murexid produces on mercury mordant a splendid purple with a violet tint, while isopurpurates dye purple having a brownish-orange tint; the colours produced by the latter are neither acted upon by sunlight nor by sulphurous acid, which quickly destroys murexid. On silk mordanted with zinc, murexid gives a fine yellow, and isopurpurates a dark, reddish-brown. Murexid colours are destroyed by acids and alkalis, whilst those of the isopurpurates assume only a yellowish tint.

Purpurates are not explosive. On adding hydrochloric acid to a somewhat concentrated solution it becomes colourless, and after some time dialuramide crystallises out. Nitric acid oxidises them to alloxan, and when caustic soda-solution is added to a solution of a purpurate, the solution becomes first bluish-violet, and on standing, or more quickly on heating, colourless.

Isopurpurates explode on heating, some very violently; on adding hydrochloric acid to a solution it becomes yellowish-brown and opaque, and afterwards brown amorphous flakes separate out. Nitric acid changes their colour to orange, and caustic soda in the cold to brownish-violet, whilst on heating, ammonia is given off, and the colour is changed to a dark, yellowish-brown. Isopurpurates are also decomposed by ammonia, but more slowly than by the fixed alkalis. Hydrogen sulphide reduces ammonium isopurpurates, sulphur separating out, while the liquid becomes yellowish-red, and assumes a dirty colour when exposed to the air. The products of decomposition of isopurpuric acid are still colouring matters, dyeing silk like the aniline-browns called Vesuvian and Bismarck.

PURPURINO-COBALT SALTS. See COBALT (p. 366).

PURPURIN. The following characteristics of this and other colouring matters of madder are given by Schützenberger (*Dingl. pol. J.* cxvii. 438).

Characters of Madder-dyes.

	Alizarin	Purpurin	Pseudopurpurin	Orange Dye	Purpuroxanthin
Absorption-bands in Spectrum	Near the Red	Near Red and in Yellow		None	None
Crystallisation	Orange needles	Red needles	Brick-red needles	From alcohol in small lumps	Yellow needles
Sublimation	Easy	Decomposed in great part		Decomposes, yielding purpurin	—
Solution in Alkalies	Purple-blue	Red	Red	Red	Yellow
Solubility in Benzol	Soluble	Soluble	Soluble	Insoluble	Soluble
Solubility in Alcohol	More soluble in hot than in cold	More soluble in hot than in cold	Very slightly soluble even in hot alcohol	Easily soluble	Soluble

The behaviour of these colouring matters in dyeing is as follows: *Alizarin* yields permanent dyes, red-violet and violet, which withstand the action of nitromuriatic acid and of soap. *Purpurin* and the *orange dye* give fast colours which withstand soap and nitromuriatic acid tolerably well; bright-red or greyish-violet. *Pseudo-purpurin* gives brick-red or pale violet colours, destroyed by soap and nitromuriatic acid. *Purpuroxanthin* gives less pure colours, orange-yellow with alumina mordants, pale grey with iron mordants.

PYRENE, $C^{10}H^{10} = C^{10}H^8(C^2H^2)$. *Phenylene-naphthalene* (Graebe, *Ann. Chem. Pharm.* clviii. 285).—A hydrocarbon occurring, together with chrysene (p. 338), in the last portions of the distillate obtained in distilling coal-tar down to coke.* The two bodies are separated by means of carbon sulphide, which dissolves the pyrene and leaves the chrysene. The carbon sulphide having been distilled off, the residue is exhausted with warm alcohol, and the cooled filtered solution is mixed with a cold alcoholic solution of picric acid as long as a red crystalline precipitate of pyrene picrate is produced. This precipitate is collected on a filter, washed with alcohol, decomposed by heating with ammonia, and the hydrocarbon thereby separated is washed with water and recrystallised from alcohol till it melts at 142° – 144° , to bring it to which point it must, in some cases, be reconverted into the picrate.

Pyrene crystallises from hot alcohol, in which it is somewhat freely soluble, in leaflets resembling those of anthracene. It often retains a yellowish colour, which may be removed by exposing its solution in benzene to sunshine. It is very soluble in benzene, ether, and carbon sulphide, and separates from benzene or ether, or by slow crystallisation from alcohol, in rather large rhombic plates. It melts at 142° , sublimes with difficulty in small plates, and distils at a temperature considerably above 360° . With very dilute *nitric acid* it forms only nitro-derivatives, no acid. With chromic acid it yields a quinone. *Hydriodic acid* converts it into hydrocarbons analogous to the hydrides of anthracene. With *bromine* it forms both substitution- and addition-products; with sulphuric acid, sulpho-acids.

Pyrene Picrate, $C^{10}H^8 \cdot C^2H^2(NO^2)_2OH$, crystallises from ether, benzene, hot alcohol, and other solvents, in long, red, shining needles, very slightly soluble in cold alcohol, somewhat abundantly in carbon sulphide and ether, very easily in benzene. It is slowly decomposed by hot water, quickly by alkalis.

Nitropyrenes.—*Mononitropyrene*, $C^{10}H^8(NO^2)$, is formed when pyrene is heated for two hours with a mixture of equal volumes of nitric acid, of sp. gr. 1.2, and water; and melts to a reddish oil which solidifies on cooling. By recrystallisation from hot alcohol, it is obtained in yellow needles, melting at 140° – 142° , slightly soluble in cold alcohol, somewhat more soluble in hot alcohol, easily in ether and in benzene. *Dinitropyrene*, $C^{10}H^6(NO^2)_2$, is obtained by boiling pyrene with nitric acid of sp. gr. 1.45, extracting the mononitropyrene formed at the same time by boiling with alcohol, and finally crystallising from glacial acetic acid. It forms slender yellow needles, slightly soluble in alcohol, ether, and benzene. *Tetranitropyrene*, $C^{10}H^4(NO^2)_4$, is formed when

* The substance described as pyrene by Laurent (l. v. 754) was doubtless a mixture of hydrocarbons containing a considerable proportion of pyrene.

dinitropyrene is boiled for a long time with nitric acid of sp. gr. 1.5, and crystallises in lustrous needles from glacial acetic acid, in which it is slightly soluble. It is almost insoluble in alcohol, and very slightly soluble in ether and in benzene. It melts at about 300°.

Bromopyrenes.—*Dibromopyrene Dibromide*, $C^{16}H^8Br^2$, is formed when finely pulverised pyrene is exposed for a day under a bell-jar to the action of bromine vapour, the bromine being kept constantly in excess. The product, crystallised from nitrobenzene, forms faintly-yellow needles soluble in aniline and nitrobenzene, nearly insoluble in alcohol, ether, and benzene.

Tribromopyrene, $C^{16}H^8Br^3$, separates in the solid state on adding a slight excess of bromine to a solution of pyrene in carbon sulphide, hydrobromic acid being evolved at the same time. It crystallises from nitrobenzene in colourless needles, which may be freed from the solvent by washing with ether. It is almost insoluble in alcohol, ether, and carbon sulphide, somewhat more soluble in benzene, easily soluble in hot nitrobenzene and aniline.

Pyrene-quinone, $C^{16}H^8O^2$.—When solid chromic acid is added to a hot solution of pyrene in glacial acetic acid, a strong reaction takes place, resulting in the formation of pyrene-quinone, the greater part of which separates during the reaction, the rest on addition of water. After washing with water, and recrystallisation from glacial acetic acid, it forms red needles or prisms. On adding water to the acetic acid solution, the quinone is precipitated as a brick-red powder very slightly soluble in alcohol, ether, benzene, and carbon sulphide, very easily in nitrobenzene. It dissolves in strong sulphuric acid, with a brown colour, and when heated with zinc-dust is reconverted into pyrene.

Hexhydropyrene, $C^{16}H^{14}$.—Pyrene is not acted on by sodium-amalgam. Heated to 200° with hydriodic acid (b.p. 127°) in presence of amorphous phosphorus, it is converted into a mixture of hydrides, from which the hexhydride may be isolated by repeated crystallisation from alcohol. It melts at 127°, does not combine with picric acid in alcoholic solution, and when passed through a red-hot tube is reconverted into pyrene.

PYRIDINE. This base is found, together with several of its homologues, in tobacco-smoke (see TOBACCO).

It is formed when the hydrochlorides of certain monomorphine derivatives are heated with potash (p. 825).

Ethylene-platinochloride of pyridene, $2(C^5H^4N.HCl).PtCl^4$, crystallises in rhombohedrons (V. v. Lang, *Chem. Centr.* 1872, 535).

PYRITES, CAPILLARY. See NICKEL SULPHIDES (p. 851).

PYRITES. On the Estimation of Sulphur in Pyrites, see SULPHUR.

PYROCATECHIN, $C^6H^4O^2 = C^6H^3(OH)^2$. This modification of dioxybenzene has hitherto been generally regarded as belonging to the meta-series or isophthalic series, 1 : 3 (p. 137); but recent investigations have rendered it more probable that it is an ortho-compound, 1 : 2 (see PHENOLS, p. 924).

Pyrocatechin has been found in living plants, e.g. in the green leaves of the Virginia Creeper (*Ampelopsis heteracea*) (Gorup-Besanzon, *Deut. Chem. Ges. Ber.* iv. 905).

Flückiger (*ibid.* v. 1) is of opinion that pyrocatechin is contained in the sap of the plants from which kino is prepared, and that it is not formed during the preparation of the kino—which consists simply in boiling down the sap—since the temperature at which this operation takes place cannot greatly exceed 100°. The residues from the ethereal extract of kino-gums from various sources gave, when dissolved in water, the characteristic pyrocatechin reaction, viz., a grass-green coloration on addition of ferric chloride, changed to red by lime-water.

Formation from Cellulose.—Hoppe-Seyler (*Deut. Chem. Ges. Ber.* iv. 18) observes that pyrocatechin is produced, together with carbon dioxide and formic acid, when paper (Swedish filter-) is heated with water to 200° for four to six hours. Paper heated to 210° in a stream of carbon dioxide gives off, as already observed by Pettenkofer, a little water and traces of formic acid, but no pyrocatechin. Starch, cane-sugar, and milk-sugar, heated with water to 280°, are carbonised, and give off comparatively larger quantities of carbon dioxide with less pyrocatechin.

When pyrocatechin is heated with *phthalic anhydride*, and water is added to the mixture, a greenish liquid is formed which exhibits, with potash, a very transient blue colour (Bayer, *Deut. Chem. Ges. Ber.* iv. 668).

Action of Bromine and Water on Bromopyrocatechin.—When tetrabromopyrocatechin is treated with bromine and water, a substance (provisionally called *oxybromopyrocatechin*) is formed, consisting of dark crimson plates, which melt at 138° and are soluble in benzene and in carbon tetrachloride. Its composition is represented by

the empirical formula, $C^{10}H^7Br^{10}O$, and it appears to be formed in the manner shown by the equation:

An ethereal solution of erythroprocatechin, treated with aqueous sodium carbonate, yields a sodium compound analogous to the corresponding derivative of xanthogallol (*q.v.*) It has a deep green colour, and brilliant metallic lustre, and decomposes readily when left in contact with alkaline solutions (Stenhouse, *Chem. Soc. J.* [2], xii. 586; xiii. 6).

PYROCHLOR. See TANTALATES.

PYROGALLOL or **PYROGALLIC ACID**, $C^6H^3O^3 = C^6H^2(OH)^1$. *Reaction with Iron Salts.*—Pyrogallol produces, in a solution of pure ferrous sulphate, a white milky precipitate which disappears on exposure to the air, the liquid turning blue. The presence of a ferric salt is therefore required to obtain the characteristic blue colour with pyrogallol, but the quantity must be small. Thus, on using a mixture containing oven 2 pts. of ferric salt to 100 of ferrous sulphate, the blue colour changed in a few minutes into red. The red solution of pyrogallol and a ferric salt deposits, on standing, a precipitate consisting first of pure purpuragallin; then a mixture of this body and tanuo-melanate of iron is obtained, and at last only the latter compound is formed.

When ammonia is gradually added to a dilute solution of ferric chloride and pyrogallol, the red solution first becomes blue and then bright red. On adding acetic acid the blue colour is restored, but changed into a greenish tint by an excess of the acid; and on addition of ammonia the liquid again becomes blue and then red. Hydrochloric acid also destroys the blue colour, the original red being reproduced. By means of this reaction the presence of 1 pt. of a ferric salt in 100,000 of water can be easily detected, and even on using only 1 c.c. containing 0.00005 gram, the liquid acquires a distinct amethyst tint. When pyrogallol is added to a solution of ferric chloride and potassium ferrieyanide containing a slight excess of the latter, a blue precipitate is formed which is soluble in water. Ammonia changes this colour into an amethyst-red, and acetic acid again into blue. When pyrogallol is added to ferric acetate or a mixture of a ferric salt and an organic salt of the alkali-metals or metals of the alkaline earths, a beautiful purplish-blue solution is obtained, which is coloured a fine red by alkalis. Organic acids restore the blue colour, while inorganic acids turn the liquid reddish-brown. The blue liquid is also formed by using ammonium succinate, gum-arabic or its compound with lime, or an alkaline solution of albumin, but not by the compounds of lime with the sugars, or by ferric acetate which has been prepared from ferric sulphate and lead acetate, and heated for some hours on a water-bath; (this solution is also without action on potassium ferrocyanide. The reaction of ammonia with pyrogallo-ferric chloride is so delicate, that by means of it 1 gram of ferric chloride will impart a purple-red colour to 2 hectolitres of water. When the blue solution is boiled, a bluish-black precipitate, insoluble in alcohol, is formed, and a similar change takes place slowly at the common temperature. A solution of pyrogallo-ferric chloride may sometimes be used in place of litmus. Thus, while red litmus is not changed by aniline, an acid solution of pyrogallo-ferric chloride assumes a beautiful blue colour on addition of aniline (Jacquemin, *Compt. rend.* lxxvii. 593; lxxviii. 1155).

Pyrogallate of Lead.—Stenhouse prepared this salt by dropping a solution of neutral lead acetate into an excess of pyrogallol, and assigned to it the composition, $3PbO.4C^6H^3O^3$ or $2C^6H^3O^3.PbO^2.PbH^2O^2.H^2O$ (i. 759)*. W. H. Doering, however, finds that the precipitate thus formed is a double salt of pyrogallate and acetate of lead, that the composition of which is the same as that $C^{12}H^6PbO^6.(C^6H^3O^3)_2Pb$, the percentage composition of which is the same as that required by Stenhouse's formula. When gently warmed with alcohol and sulphuric acid, it gives off acetic ether, in quantity very nearly equal to that which should be produced from a salt having the composition just stated. It is possible that many insoluble lead salts of organic acids prepared by precipitation from lead acetate, and said to be basic salts containing *m* molecules of lead salt + *n*PbO, may really be double salts containing lead acetate (*Chem. Soc. J.* [2], xi. 702).

Oxidation of Pyrogallol.—*a. By Electrolysis.*—Pyrogallol is easily oxidised by electrolysis. At first, the oxygen eliminated at the positive pole is entirely absorbed; afterwards carbon dioxide is evolved in large quantity, and ultimately a mixture of this gas with oxygen and carbon monoxide.

B. By Active Oxygen.—H. Struve (*Ann. Ch. Pharm.* clxiii. 160) finds that pyrogallol undergoes slow oxidation when its aqueous solution is mixed with lead dioxide, gum arabic, extract of malt, grape-juice, colouring matter of blood, or saliva, and exposed

* There printed erroneously $C^{12}H^6PbO^6.PbH^2O^2$.

to the air. In presence of either of these substances, a dilute solution of pyrogallol gradually assumes a wine-yellow, or even a darker colour, and deposits small yellow capillary needles of purpurogallin (*1st Suppl.* 977), the solution remaining clear throughout. Cane-sugar, grape-sugar, starch, pepsin, and urine do not act in this way.

The easiest way of setting up this reaction is to mix 50 c.c. of a 1 p.c. solution of gum arabic* with 0.2 p.c. pyrogallol. The pyrogallol dissolves almost immediately, and the separation of purpurogallin begins after a few hours. A solution of purpurogallin is coloured deep blue by alkalis, as previously observed by Girard, and the reaction may serve for the detection even of very small quantities of this body. If, however, the purpurogallin is still contaminated with traces of pyrogallol or with other products of decomposition, it is coloured more or less brownish by alkalis. Purpurogallin, like pyrogallol, gives Trommer's reaction with cupric sulphate and an alkali.

As gum reacts with pyrogallol in a similar manner to blood, Struve infers that it discharges in plants a function similar to that of blood in the animal organism—that is to say, it acts as a carrier of oxygen.

When ozonised oil of turpentine is shaken up with pyrogallol, purpurogallin is formed, and dissolved by the turpentine. On agitating this oil with water, and a few drops of ammonia, the water acquires a transient blue colour.

Struve adduces experiments which demonstrate the incorrectness of Schönbein's statement (*Jahresb. f. Chem.* 1860, 55), that hydrogen dioxide can exist in contact with pyrogallol, and that during the oxidation of a solution of pyrogallol mixed with caustic soda, hydrogen dioxide is formed in the liquid. Struve further observes that, when solutions of pyrogallol in pure water, or in water containing potash or gum, are exposed in large glass flasks to the action of the air, best in sunshine, and strips of ozone-paper are suspended in the flasks, a very distinct ozone reaction becomes manifest in a few hours.

According to J. D. Boeke (*Deut. Chem. Ges. Ber.* vi. 486; *Chem. Soc. J.* [2], xi. 1031), pyrogallol dissolved in aqueous potash (1 mol. pyrogallol to 3 mols. potassium hydrate), and exposed to the action of ozonised air, is converted into an acid having the composition $C^6H^4O^7$.

γ. By Chromic Acid.—According to Wichelhaus (*ibid.* v. 846) pyrogallol is converted by oxidation with chromic acid into a product difficultly soluble in chloroform and benzene, and crystallisable with some difficulty from alcohol. Wichelhaus regards this product as identical with Girard's purpurogallin, but assigns to it the formula:

Reaction with Quinone.—Pyrogallol dissolves quinone, forming pyrogalloquinone, $C^6H^4O^8$. The reaction is:

Pyrogalloquinone is a red crystalline substance, which does not melt below 200° , and may be sublimed, but not without considerable loss. It is decomposed by alkalis, yielding blue solutions which soon turn black (Wichelhaus, *loc. cit.*)

Reactions with Aldehydes.—When pyrogallol is dissolved in aqueous *methylens acetate*, not in excess, and fuming hydrochloric acid is added—whereby formaldehyde is produced (p. 533)—the liquid quickly solidifies, from separation of a body which is soluble in water but insoluble in hydrochloric acid, and precipitates gelatin. If formaldehyde is present in excess, the precipitate, which is at first white, immediately turns red, forming a very permanent dye-stuff. The amorphous, colourless body boiled with dilute hydrochloric or sulphuric acid yields small, colourless needles, which appear to be insoluble in water. If the boiling be continued too long, the liquid and the crystalline compound become dark-coloured. An analysis of the compound gave 68.18 p.c. carbon and 4.66 hydrogen (Baeyer, *Deut. Chem. Ges. Ber.* v. 1096).

Acetaldehyde-ammonia dissolved in hydrochloric acid gives, on addition of strong hydrochloric acid, a white precipitate consisting of a greasy substance easily soluble in water. On heating a mixture of aldehyde, hydrochloric acid, and pyrogallol, a red substance is produced. Chloral reacts with pyrogallol like aldehyde (Baeyer, *ibid.* 26).

* Gum which has been treated with hydrochloric acid is indifferent towards pyrogallol; but it does not become inactive by purification with acetic acid, or by the boiling of its solution.

On mixing *furfural* with pyrogallol and moistening with a trace of hydrochloric acid, an indigo-blue substance is formed, which dissolves in water with green colour and is precipitated by hydrochloric acid in blue flocks (Bayer, *ibid.* 25).

Benzaldehyde heated with pyrogallol yields, as chief product, a colourless, resinous compound, $C^{26}H^{22}O^7$, which crystallises from solution in ether. At the same time, there is formed a red oxidation-product which dyes calico like gallein, but bluer, and is converted by reducing agents into the colourless body just mentioned. This substance, heated to 200° , gives off hydrogen, and is converted into a red compound, $C^{26}H^{20}O^7$, which dissolves with dark red colour in alcohol. The colourless body is immediately obtained pure by mixing a cold solution of pyrogallol in hydrochloric acid with a well-shaken mixture of benzaldehyde and a very large quantity of hydrochloric acid. The clear solution becomes turbid in a few seconds, and deposits the substance in question in the perfectly colourless state. On heating the mass with hydrochloric acid, part of it turns red, while another portion is converted into the crystalline compound. The latter is at once obtained perfectly pure by adding highly concentrated hydrochloric acid by small portions to a boiling solution of pyrogallol and benzaldehyde in a large quantity of absolute alcohol, till the crystalline precipitate which forms after a while no longer alters. The whole is then to be quickly cooled, left to itself for a day, and the precipitate washed with alcohol. The body thus obtained is perfectly colourless, almost insoluble in alcohol, slightly soluble in acetone, crystallises in obliquely truncated prisms, and has the same composition as the resinous body formed in the cold, viz., $C^{26}H^{22}O^7$, its formation being represented by the equation:

If, in the last experiment, *salicyl*ol be used instead of benzaldehyde, a similar reaction takes place. Only a small quantity of alcohol must, however, be used, since the resulting compound is easily soluble therein. This compound is colourless, crystallises in six-sided tables, and has the composition $C^{26}H^{22}O^8$, its formation being represented by the equation:

(Bayer, *ibid.* 280).

Action of Bromine, in presence of Water, on Tribromopyrogallol (Stenhouse, *Chem. Soc. J.* [2], xii. 586; xiii. 1).—When tribromopyrogallol is added to about twice its weight of bromine and then 5 to 10 pts. of water are poured on the mixture, there is a slight development of heat, and both the bromine and the bromopyrogallol dissolve, forming a deep orange-coloured solution. If this be heated to 70° – 80° , it begins to effervesce from evolution of carbonic anhydride, and a substance is gradually deposited in bright yellow crystalline plates which have a composition represented by the formula, $C^4H^2Br^2O^3$, or rather, $C^4H^4Br^4O^6$, the reaction being:

After purification by crystallisation from carbon sulphide and light petroleum, it forms brilliant yellow plates which melt at 122° , and are very soluble in ether, benzene, and carbon sulphide. It is also soluble in alcohol, but undergoes decomposition at the same time. This substance, called provisionally *Xanthogallol* (*q. v.*), is better prepared by the action of bromine and water on pyrogallol itself.

If, instead of treating the bromopyrogallol with twice its weight of bromine, only one part be added, the whole dissolves as before on addition of water, forming an orange-coloured solution. On allowing this to stand for a short time at the ordinary temperature, colourless scales begin to separate, and gradually increase until the mixture, if sufficiently concentrated, becomes semi-solid. The substance thus formed is somewhat soluble in water, and decomposes when gently heated. It does not appear to be converted into the yellow compound when treated with excess of bromine.

PYRIGOALLOQUINONE. See the last article.

PYROMELLITIC ANHYDRIDE. On the action of this compound upon naphthol, and the composition of the resulting naphtholic pyromelliteins, see p. 840.

PYROMORPHITE. The following are recent analyses of this mineral: 1, 2, 3, from Chester Co., Pennsylvania; 1, dark olive-green; 2, yellowish-green; 3, somewhat darker than 2 (Williams, *Chem. News*, xxi. 84):

	$3PbO.P^2O^5$	$3CaO.P^2O^5$	$3FeO.P^2O^5$	$PbCl^2$	CaF^2	Insol.
1.	87.40	0.37	1.74	9.79	0.84	0.42 = 100.00
2.	85.89	2.64	0.62	9.41	0.67	trace = 99.23
3.	87.01	trace	1.39	9.13	0.91	trace = 98.14

These specimens contained a small quantity of silver, estimated at 0.0037 p.c.
4. From Shapbach, in the Schwarzwald, containing traces of fluorine and of cupria

oxide, to the latter of which the beautiful apple-green colour of the mineral is evidently due. Sp. gr. = 6.416 at 20°.

	P ² O ⁵	As ² O ⁵	PbO	CaO	Pb	Cl
4.	16.25	0.61	68.60	3.28	7.95	2.62 = 99.31

(Petersen, *Jahrbuch f. Mineralogie*, 1871, 393).

Specimens of pyromorphite from Cumberland have been found to contain didymium, the quantity of which, judging from the intensity of the absorption-bands, is about equal to that in asparagus stone (C. Horne, *Chem. News*, xxvi. 109).

PYROMUCIC ACID, C⁴H⁴O⁸ (Limpricht, *Ann. Chem. Pharm.* clxv. 278). This acid is produced in small quantity only by the dry distillation of mucic acid, and is best obtained by the action of alcoholic potash on furfural. By distilling it with phosphorus pentachloride a mixture of different bodies is formed which could not be separated. When the barium salt mixed with soda-lime is heated, a compound called tetraphenol, C⁴H⁴O⁴, distils over. It is a colourless liquid, having a peculiar smell, and boiling at 32°. Tetraphenol is not acted upon by alkalis, and its alcoholic solution is not precipitated by lead or silver salts. Sodium and potassium have no action upon it, nor is it changed by passing carbon dioxide into its ethereal solution containing sodium, or by heating it with sodium and carbon dioxide in a closed tube. It does not combine with the bisulphites of the alkali-metals, and remains unaltered when sodium-amalgam is added to its alcoholic solution. Acids act readily on it; concentrated hydrochloric decomposes it with the greatest violence, and dilute acids more slowly, with formation of the so-called pyrrol-red:

When 2 mols. of bromine are added to a solution of 1 mol. of pyromucic acid, carbon dioxide is evolved, and a very small quantity of an oily liquid separates out. By shaking the aqueous solution with ether, evaporating the ethereal solution on a water-bath, and drying the residue over sulphuric acid, a yellowish syrup is left behind, from which, on standing, white warty crystals, having the composition C⁴H⁴O⁸, separate out. This body has an acid reaction, and its solution is coloured yellow by excess of alkali. When baryta-water is added until the liquid has only a faint acid reaction, alcohol produces a white precipitate having the composition (C⁴H⁴O⁸)₂·Ba. An excess of baryta-water produces a yellowish precipitate, the quantity of which increases on heating the solution, which has the same composition. The compound, C⁴H⁴O⁸, is also formed by the action of lead oxide or potassium dichromate and dilute sulphuric acid on pyromucic acid; by acting with sodium-amalgam on its aqueous solution, the bodies C⁴H⁴O⁸ and C⁴H⁴O⁶ were formed, and bromine oxidises it to fumaric acid, which appears to be also formed by boiling it with water and silver oxide. It seems probable therefore that the compound C⁴H⁴O⁸ is the aldehyde of fumaric acid, although it does not combine with the bisulphites of the alkali-metals.

The compound C⁴H⁴O⁸ is not always formed by the action of 2 mols. of bromine on pyromucic acid and water, but several times the body C⁴H⁴BrO⁸ was produced, which is formed according to the following equation:

This compound forms white feathery crystals melting at 84°, and smelling like camphor. It readily volatilises with the vapour of water, and is soluble in ether and alcohol, but not in water. Alcoholic potash does not act on it at 180°. By adding sodium-amalgam and sulphuric acid to an alcoholic solution, the compound C⁴H⁴O⁸ is formed, a heavy very refractive liquid, smelling like benzene, which is not acted on by hydrochloric acid and alkalis, and does not combine with alkaline bisulphites.

When an excess of bromine is added to pyromucic acid in presence of water, mucobromic acid, C⁴H⁴Br²O⁸ (p. 828), is formed:

Isopyromucic Acid, C⁴H⁴O⁸, is produced, together with pyromucic acid, a small quantity of an empyreumatic oil, formic acid, water, carbon dioxide, carbon monoxide, and a gas burning with a luminous flame, by the dry distillation of mucic acid. The operation must be performed in a retort, of which only one-sixth is filled, and heat is applied, first very slowly, so that only one drop passes over every two minutes; afterwards the retort is gradually heated to a dull red-heat. It takes about eight hours to decompose 30 grams of mucic acid. Isopyromucic acid decomposes carbonates but slowly, and may therefore easily be separated from the other acids by digesting the distillate with barium carbonate, and shaking the solution with ether. It is readily soluble in water, and sublimes slowly at 100° in a current of carbon dioxide, in small plates softening at 70°, and becoming perfectly liquid at 82°. It is a monobasic acid.

Its aqueous solution is coloured brown by alkalis; baryta-water in excess produces a bulky precipitate, and, on boiling, the solution acquires a deep-red colour. On adding bromine to the aqueous solution of the acid, a crystalline body insoluble in water is formed, together with mucobromic acid (Limpriecht).

Stenhouse (*Chem. News*, xxiv. 303) describes another isomeric acid of pyromucic acid, distinguished as β -pyromucic acid, the silver salt of which he obtained by digesting fucosol (ii. 918) at 100° with recently precipitated silver oxide and water. The acid separated from this salt by precipitating the silver with hydrochloric acid, and evaporating the solution at 100° , is a brown semi-crystalline mass, from which petroleum-ether extracts the acid, leaving the colouring matter undissolved. The acid thus separated may be purified by one or more crystallisations from boiling water. It crystallises from aqueous solution in rhombic plates melting at 130° , whereas ordinary pyromucic acid, prepared from furfural, crystallises in smooth needles, and melts at 133° . Silver β -pyromucate, $C^3H^2AgO^4$, is moderately soluble in boiling water, and separates, on cooling, in long flat needles.

PYROPHOSPHATES. On the formation of these salts by the decomposition of hypophosphites, see p. 966.

PYROPHOSPHORIC SULPHOBROMIDE, $P^2S^2Br^4$. See PHOSPHORUS COMPOUNDS (p. 963).

PYRORACEMIC or **PYRUVIC ACID**, $C^3H^3O^4$. *Action of Phosphorus Pentachloride.*—When 4 or 5 pts. of the pentachloride are gradually added to 1 pt. of pyroracemic acid, the mixture being ultimately warmed till all the pentachloride is dissolved, the cooled liquid treated with alcohol till hydrochloric acid ceases to escape, and then mixed with a large quantity of water, a red-brown oil separates, which, after washing with water, and drying with calcium chloride, distils at 160° , yielding ethyl dichloropropionate, $C^3H^2Cl^2O^2.C^2H^5$, as a colourless liquid having a specific gravity of 1.2493 at 0° . Dilute aqueous ammonia converts this ether into a white crystalline mass melting at 116° , and having the composition $C^3H^2Cl^2NO$ (Klimenko, *Deut. Chem. Ges. Ber.* iii. 465).

Böttger (*ibid.* vi. 893), by adding phosphorus pentachloride to pyroracemic acid cooled by a freezing mixture, treating the product with alcohol, and subsequently distilling, obtained a distillate of ethyl acetate, and a residue from which water separated ethyl dichloropropionate.

When pyroracemic acid is heated with water to 130° , a small quantity of carbonic anhydride is evolved, probably due to the formation of a trace of pyrotartaric acid, but the bulk of the pyroracemic acid remains unchanged. When, however, the heat is raised to 160° , a considerable quantity of carbonic anhydride is evolved, and products not yet investigated are formed (Böttger, *ibid.* vi. 787). With baryta-water pyroracemic acid yields acetic and oxalic acids, besides urtic acid, $C^3H^3O^4$ (v. 971) (Böttger, *loc. cit.*)

Barium peroxide acts violently on pyroracemic acid, forming the barium salt of an acid containing $C^3H^3O^8$, probably formed according to the equation $3C^3H^3O^4 - H^2O = C^3H^3O^8$. When pyroracemic acid is heated with strong nitric acid, oxalic acid is formed, together with small quantities of formic and carbonic acids (Böttger, *ibid.* vi. 790).

When pyroracemic acid, partly neutralised with baryta, is heated with water to 130° for several hours, an acid, $C^3H^3O^4$, containing 2 at. hydrogen more than urtic acid, is obtained in shining crystals melting at 133° and volatilising completely when heated on platinum-foil (Böttger, *ibid.* 893).

Wislicenus, by acting on 1 mol. pyroracemic acid with 2 at. bromine, obtained a crystalline acid, $C^3H^2Br^2O^4$, which was transformed into lactic acid by nascent hydrogen and was therefore probably dibromolactic acid (iv. 770). According to P. de Clermont (*Bull. Soc. Chim.* [2], xix. 103) this acid, when acted upon in the fused state by chlorine, evolves hydrochloric acid, and yields a product which crystallises from its aqueous solution in large, flat, rhombic crystals, efflorescent in the air and in a vacuum, and melting at about 93° . This product is free from chlorine, but contains bromine, and, notwithstanding discrepancies in analysis, De Clermont believes it to be identical with the dibromopyruvic acid of Wichelhaus, $(C^3H^2Br^2O^4)$, with which it agrees in properties:

Pyroracemic acid, heated to 100° for some time with hydrochloric acid in a sealed tube, undergoes decomposition, carbon dioxide being formed in abundance. The liquid yields, on evaporation, crystals having the composition of pyrotartaric acid, and melting at 110° – 112° (De Clermont).

Sulphopyrroacemic acid, heated to 100° with aqueous solution of bromine in a sealed tube, yields a syrupy, non-crystallisable, brominated acid. Sulphopyrroacemate of barium, submitted to the same treatment, yields bromosulphopyrroacemate of barium, crystallisable, and soluble in water (De Clermont).

Pyroacemic Ethers.—Pyroacemic acid does not yield an ether by treatment with alcohol and hydrochloric or sulphuric acid; neither is the ethylic ether obtained by acting on the silver salt with ethyl iodide diluted with dry ether, the only results of the reaction being free pyroacemic acid and condensation-products. Methyl iodide, on the other hand, yields a pyroacemic ether when similarly treated, but even in this case much of the acid is liberated.

Methyl pyrroacemate, $C^2H^2(OH^2)O^2$, is a liquid boiling between 134° and 137° , having a sp. gr. of 1.154 at 0° , and an odour like that of acetone. With acid sodium sulphite it becomes hot, but does not yield a crystalline product.

The structural formula of pyroacemic acid is most probably $CH^2.CO.CO.OH$, and that of the methylic ether, $CH^2.CO.CO(OC^2H^3)$ (Oppenheim, *Deut. Chem. Ges. Ber.* v. 1051).

PYROSULPHOPHOSPHORIC ETHERS. See SULPHOPHOSPHORIC ETHERS.

PYROSULPHURIC ACID and **CHLORIDE.** See SULPHUR, OXYGEN-ACIDS OF.

PYROVANADATES. See VANADATES.

PYROTARTARIC ACID, $C^2H^2O^4$. *Fermentation.*—According to Béchamp (*Compt. rend.* lxx. 299), calcium pyrotartrate fermented in contact with microzymo chalk (1st Suppl. 614) gives off marsh gas and carbon dioxide.

Action of Bromine (Lagermark, *Zeitschr. f. Chem.* vi. 299).—Bromine acts very slowly on pyrotartaric acid at ordinary temperatures, but when 10 pts. of pyrotartaric acid, 24 pts. bromine, and 10 c.c. water, are heated together to 120° , the bromine disappears in about 6 hours, and on cooling there is obtained (together with CO^2), a pale yellow liquid, and mostly a white mass of monobromocitraconic anhydride, $C^2H^2BrO^3$ (p. 348). On mixing the liquid with 4 or 5 vols. water, crystals separate after some time, consisting of bromoxaform (pentabromomethyl acetate), formed according to the equation:

The bromocitraconic anhydride is supposed to be produced from previously formed dibromopyrotartaric acid; thus:

Bromocitraconic anhydride is also formed, together with a dark greasy mass, when pyrotartaric acid is treated with dry bromine at 100° .

Bromine in presence of water acts but slowly on silver pyrotartrate at ordinary temperatures, but easily at the heat of the water-bath, nothing, however, being produced except pyrotartaric acid, silver bromide, and carbon dioxide. Dry bromine acts on silver pyrotartrate, separating the silver as bromide, and on exhausting with alcohol, and evaporating, there remains a mixture of pyrotartaric acid and anhydride. When 1 mol. pyrotartaric acid is heated with 1 mol. bromine in presence of water, a small quantity of carbon dioxide is evolved, and the only other product formed is bromocitraconic anhydride (soluble in ether), half the pyrotartaric acid (insoluble in ether) remaining unattacked. The same reaction takes place when pyrotartaric acid is treated with an equal volume of bromine without water, excepting that in this case a thick black mass is formed, from which nothing but bromocitraconic anhydride can be separated.

Tribromopyrotartaric acid, $C^2H^2Br^3O^4$.—The only way of obtaining brominated pyrotartaric acid is to heat the pyrotartaric acid with excess of bromine. 1 mol. of the acid and 5 to 6 mols. bromine are heated in presence of water to 120° for three hours, the mixture then left to cool, well shaken, and heated in a flask with a drawn-out neck, till the vapour in the point of the tube appears only light-red; if the process is not conducted in this manner, carbonisation, and still more easily explosion, may take place. On opening the tube, hydrogen bromide and carbon dioxide escape. The resulting solid white mass consists of tribromopyrotartaric acid, which, after washing, pressing and recrystallisation from water, separates from its solution by slow evaporation in six-sided prisms having a strong acid reaction. It does not melt at 240° , but sublimes without previous fusion at a higher temperature.

Silver tribromopyrotartrate, $C^2H^2Br^3Ag^2O^4$, is a white precipitate, insoluble in water,

permanent in the air, anhydrous at 100°. The potassium salt is an amorphous glassy mass, easily soluble in water.

Isomerides of Pyrotartaric acid.—Wislicenus (*Ann. Ch. Pharm.* cxlix. 220) has converted bromobutyric acid, $C^4H^7BrO_2$, into an acid isomeric with pyrotartaric acid, by treating its ethylic ether first with potassium cyanide, then with potassium hydrate:

and

The products of this reaction are a crystallised acid melting at 111°–112°, and, in larger quantity, a syrupy acid whose neutral ammonia salt is precipitated by lead and mercuric salts, but not by zinc, copper, cadmium, or ferric salts. Both these acids have the composition $C^4H^7O_4$. Hence Wislicenus infers that in the bromination of butyric acid, two isomeric acids are formed—namely, α -bromobutyric acid, $CH^3.CH^2.CHBr.CO^2H$, which may be converted into syrupy ethyl-malonic acid, $CH^3.CH^2.CH(CO^2H)^2$; and, in smaller quantity, β -bromobutyric acid, $CH^3.CHBr.CH^2.CO^2H$, which, by the process above described, is converted into another isomeride of pyrotartaric acid represented by the formula, $CH^3.CH(CO^2H).CH^2.CO^2H$. The first of these isomeric acids has likewise been obtained from α -bromobutyric acid by Markownikoff and Tupoleff (*Deut. Chem. Ges. Ber.* v. 329), who find that it is resolved by heat into butyric acid and carbon dioxide.

PYRRHITE. According to A. Schrauf (*Jahrb. f. Mineralogie*, 1871, 764), the pyrrhite of San Miguel (zirconium niobate, iv. 783) exhibits distinct octohedral faces. Hardness = 5.5. A characteristic blowpipe reaction, serving especially to distinguish pyrrhite from pyrochlore, is that pyrrhite forms with microcosmic salt in the oxidising flame a bead which is perfectly clear and colourless, whether hot or cold, whereas the bead formed by pyrochlore is yellow while hot, and becomes colourless only on cooling.

PYRROL. Pyrrol-bases appear to be present, together with bases of the pyridine series, in tobacco-smoke (see **TOBACCO**).

Pyrrol-red, $C^{12}H^{10}O^2$, is formed by the action of acids on tetraphenol (p. 1032).

Q

QUARTZ. This mineral has been found, together with iron-glance, in the clefts of a trachytic lava from Lipari, in small crystals exhibiting all the marks of volcanic sublimation (*G. vom Rath, Pogg. Ann.* cxlvii. 272).

The formation of quartz in small prisms, together with that of a felspar allied to oligoclase, has been observed by H. Benrath (*Jahresb. f. Chem.* 1871, 1139) during the devitrification of lime-soda glasses.

The colour of *smoky quartz* (smoky topaz) has sometimes been attributed to allotropic modification of the silica. Flückiger (*Jahresb.* 1871, 1199), on the other hand, from the examination of very large crystals of smoky quartz from the Tiefen glacier in Switzerland, concludes that the colour is due to organic matter; and this conclusion has been confirmed by A. Forster (*Pogg. Ann.* cxliii. 173), who has shown, by optical examination and determination of density, that the colour cannot be due to allotropic modification, and that the smoky quartz, when subjected to dry distillation, yields a small quantity of a brownish liquid containing ammonium carbonate, whence it would appear that the colour is due to an organic body containing nitrogen.

On the crystalline forms of quartz from various localities, see *Jahresb. f. Chem.* 1870, 1277; 1871, 1138.

QUARTZ-PORPHYRY. The following are analyses of this rock from the neighbourhood of Teplitz in Bohemia (*Wien. Akad. Ber.* [2 Abth.], lxi. 755; lxiii. 325):

A. From a quarry. Coarse-grained ground-mass, enclosing numerous quartz-grains and a small quantity of black mica. Sp. gr. = 2.64. Analysed by J. Stingl.

B. Near the foot of the Königshöhe. Decomposed. The ground-mass contains kaolinised orthoclase and coarse-grained quartz. Sp. gr. = 2.58. a. Soluble. b. Insoluble. Analysed by H. Wieser.

C. From the banks of the Saubach. Completely disintegrated. Sp. gr. = 2.512.
a. Soluble. b. Insoluble. Analysed by J. Stingl.

D. Another variety from the banks of the Saubach. Sp. gr. = 2.567. Analysed by J. Stingl.

	SiO ²	Al ² O ³	Fe ² O ³	MnO	CaO	MgO	K ² O	Na ² O	H ² O	
A.	73.09	11.61	7.62	0.88	—	0.90	3.19	2.19	0.70	= 100.27
B. { a.	0.30	3.00	0.45	—	—	—	0.58	1.66	3.20	= 99.34
b.	67.81	20.47	0.85	—	1.46	0.06	—	—	—

QUININE. QUINIDINE. QUINICINE. QUINAMINE. See CINCHONABASMS (pp. 343-346).

QUINOA. The bitter seeds of red quinoa, grown in the gardens of Lima, were found by M. C. Cooke (*Pharm. J. Trans.* [3], iii. 281) to contain:

	per cent.		per cent.
Water	16.01	Casein and a small quantity	
Starch	38.72	of insoluble albumin . . .	7.47
Sugar and extractive		Insoluble albumin and other	
matters	5.12	proteids	11.71
Gum	3.94	Vegetable fibre	7.99
Oil	4.81	Inorganic matter	4.23

QUINONE, C⁶H⁴O². Vapour-density.—Hofmann (*Deut. Chem. Ges. Ber.* iii. 583) has determined the vapour-density of quinone in a barometric vacuum at the temperature of aniline vapour; and has obtained the numbers 51.7 and 53.73 (H=1), agreeing nearly with the number 54 calculated from the formula C⁶H⁴O².

Quinone volatilises completely at the temperature of boiling aniline; its vapour has a faint yellow colour, and condenses, on cooling, in long yellow needles, which exhibit no sign of decomposition.

Dichloroquinone, C⁶H²Cl²O², is formed, with evolution of hydrochloric acid, by the action of nitric or nitrous acid on trichlorophenol:

(Faust, *Zeit. f. Chem.* 1867, 727; Weselsky, *Deut. Chem. Ges. Ber.* iii. 646). It crystallises from alcohol in straw-yellow prisms an inch long; has a peculiar aromatic odour; colours the skin reddish-brown; melts at 120°; sublimates at a much lower temperature; and gives, with ammonia, a solution gradually turning green, reddish, and finally brown, from which acids no longer precipitate dichloroquinone. Ferric chloride added to its aqueous solution throws down slender white needles (Faust).

Dichlorodioxyquinone. Chloranilic acid, C⁶Cl²(OH)²O².—This substance, fused with potash at 150°–170° in a stream of hydrogen, yields potassium chloride and oxalic acid. When potassium chloranilate is heated to 170° with potassium acetate and water, or with water alone, carbon dioxide is formed and a large quantity of carbon separated. Potassium chloranilate detonates when heated alone, likewise yielding carbon dioxide and free carbon:

(Morz a. Woith, *Deut. Chem. Ges. Ber.* v. 462).

Hydroquinone, C⁶H⁴O² = C⁶H⁴(OH)².—On the structure of this compound and its isomerides, pyrocatechin and resorcin, see PHENOLS (p. 924); also Hesse (*Deut. Chem. Ges. Ber.* v. 1022; *Chem. Soc. J.* [2], xi. 386).

Hydroquinone heated with phthalic and sulphuric acids forms a red phthalein, which dissolves in potash with a red colour, and dyes iron and alumina mordants like barwood (Grabowsky, *Deut. Chem. Ges. Ber.* iv. 658).

Phenoguinone. When 1 pt. of phenol, C⁶H⁵O, dissolved in water, is digested with 2½ pts. chromic acid for half-an-hour, chromic oxide separates, and on distilling the solution, a yellow watery liquid passes over; and on agitating this with ether and evaporating the ethereal solution, a dark-red crystalline mass is obtained which, by pressure and sublimation, yields beautiful red needles, with green metallic lustre, consisting of phenoguinone:

The formation of this substance is due to the oxidation of part of the phenol to quinone, and the combination of this body with phenol deprived of 2 at. hydrogen by further oxidation:

and

In fact, on adding quinone to a solution of phenol, the same red compound is obtained, but various reduction-products are formed at the same time, including apparently green quinhydrone.

Phenoquinone melts at 71°, dissolves in water, more readily in alcohol and ether; it is not altered by chromic acid in the cold; does not form salts. It splits up, under the influence of heat and of various reagents, into phenol and quinone, or the products of their decomposition (Wichelhaus, *Deut. Chem. Ges. Ber.* v. 248).

All the phenols of the aromatic series (cresol, thymol, resorcin, α -naphthol, β -naphthol, &c.) react with quinone in a similar way; thymoquinone also reacts thus, but the difficultly reducible anthraquinone does not undergo such changes. Chloroquinone and thiophenol do not develop substitution-products in this manner; trichlorinated quinone is reduced, and the chlorine removed, by the action of pyrogallie acid; tetrachloroquinone, on the other hand, does not lose any chlorine, but forms tetrachloro-hydroquinone; thiophenol reduces the quinone to quinhydrone, and finally to hydroquinone.

Phenoquinone, treated with *aniline*, forms a crystalline product similar in constitution to itself, being derived from it by substitution of NH for O:

This body is identical with Hofmann's quinone-anilide, obtained by the action of quinone on aniline. Hofmann regarded it as $C^{12}H^{14}O^2N^2$, whereas Wichelhaus assigns to it the above formula, $C^{12}H^{14}O^2N^2$.

Pyrogallol dissolves quinone, producing red crystalline pyrogallol-quinone, $C^6H^4[O.O.C^6H^4(OH)^2]^2$, already described (p. 1030).

Quinhydrone or *Green Hydroquinone* is regarded by Wichelhaus as

above considered. This formula agrees well with Wöhler's analysis of quinhydrone; nevertheless, this body is generally regarded as $C^{12}H^{10}O^4 = C^6H^4O^2.C^6H^4O^2$ (Wichelhaus, *Deut. Chem. Ges. Ber.* v. 840).

On *Naphthaquinone*, see p. 825.

On the isomeric bodies, *Anthraquinone*, *Phenanthrene-quinone*, and on the constitution of Quinones in general, see pp. 90-95.

QUINTANES, C^6H^{12} . See AMYL HYDRIDES (p. 63). It is there suggested that tetramethyl-methane, $C(CH^3)^4$, might be obtained by the action of zinc-methyl on dichloropropane or methyl-chloracetol, $CH^3-CCl^2-CH^3$; and indeed Lwow (*Zeitschr. f. Chem.* [2], vii. 257) has actually obtained by this process a gas having the composition C^6H^{12} ; but it does not crystallise at -30° , whereas that which he formerly obtained by the action of zinc-methyl on tertiary butyl iodide (*ibid.* vi. 521) solidified at -20° . The later product was perhaps impure.

R

RABDIONITE. A soft black graphic mineral, occurring in the form of small bars at Nischne-Tagilsk in the Ural. When rubbed with the finger, it acquires a fatty lustre. It melts easily before the blow-pipe to a steel-grey magnetic bead, by which property and by its large amount of iron it is distinguished from asbolan. Sp. gr. = 2.80. Analysis gave:

FeO*	MnO*	Al ₂ O ₃ *	CaO	MnO	CaO	H ₂ O
45.0	18.00*	1.40	14.0	7.61	5.10	13.50 = 99.61

* Another experiment gave 14.00.

(F. v. Kobell, *J. pr. Chem.* [2], i. 428).

RACEMIC ACID. On the reciprocal transformation of racemic and inactive tartaric acid, see TARTARIC ACID.

RAIN. On the composition of Rain-water, see ATMOSPHERE (p. 112). On the quantities of nitrous and nitric acid in rain-water, see NITRIC ACID (p. 857); also *Chem. Soc. J.* [2], x. 87, 281, 324.

RALSTONITE. A hydrated aluminium fluoride containing traces of sodium and calcium, from the cryolite formation of Arksut Fjord in Greenland. It crystallises in regular octohedrons (sometimes with very subordinate dodecahedral faces); colourless, and with a vitreous lustre. Hardness above 45. Sp. gr. = 2.4. It appears to be chemically related to *fluellite*, which crystallises in rhombic forms (G. J. Brush, *Sill. Am. J.* [3], ii. 30).

RAMMELSBERGITE (F. Sandberger, *Jahrb. f. Mineralogie*, 1871, 935).—This mineral, the rhombic form of nickel diarsenide, NiAs₂, hitherto found only at Schneeberg in Saxony, has lately been found at Wittichen in Baden. A specimen analysed by A. Hilger gave results agreeing nearly with the former analysis by E. Hofmann (iv. 37).

	As	Ni	Fe	Bi	Cu	Co	S
Hilger	68.80	26.65	2.06	2.66	trace	trace	trace = 99.67
Hofmann	71.30	28.14	—	2.19	0.50	—	0.14 = 102.27

Deducting the bismuth, and reckoning the iron as nickel, both analyses lead to the formula NiAs₂, which requires 72.15 p.c. As, and 27.85 Ni. The mineral becomes covered by weathering with a very light green crust, appearing under the microscope as a mixture of glistening white octohedrons of arsenious oxide and green lustreless nickel arsonate (nickel-bloom).

In the specimen analysed by Sandberger the rammelsbergite is coated with a crust of steel-grey smaltine, CoAs₂, which is intimately mixed with quartz, very hard, and shoots out on the surface into larger crystals, ∞ O ∞ . O. Besides cobalt and arsenic, it contains a large quantity of iron, with very little nickel, copper, and sulphur. It is evidently identical with the mineral from the Sauschwart mine at Schneeberg, analysed by E. Hofmann, and containing 0.66 p.c. S, 1.39 Cu, 0.01 Bi, 70.37 As, 11.71 Fe, 1.79 Ni, and 13.95 Cu. The surface of separation of the two minerals does not exhibit a regular curvature, as if one of them had been deposited over the other, but is irregular and jagged, as if the arsenides of the several metals had been first precipitated together, and separated by subsequent molecular action, in such a manner as to concentrate the nickel in the interior. Precisely similar appearances are presented in the occurrence of copper-nickel with smaltine and cloanthite, the copper-nickel forming the irregularly bounded nucleus of a spheroid, and containing only traces of cobalt, which, on the other hand, is concentrated with the iron, and without any nickel, in the outer crust. A specimen from Wittichen was found to contain:

	Ni	Co	Fe	S	As
In the nucleus (copper-nickel)	43.86	trace	0.67	1.18	53.40
In the crust (smaltine)	8.52	10.11	5.05	4.71	89.70

RAPAKIVI or RABAKIWI. A variety of granite occurring at Pyterlak and other localities in Finland (v. 77). Analyses α and δ are by Struve; ϵ by Benrath, of a weathered friable variety from Pyterlak.

SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	MnO	CaO	MgO	K ₂ O	Na ₂ O	H ₂ O
75.06	0.36	11.70	1.04	1.57	trace	1.01	0.19	6.25	2.56	0.63 = 100.37
77.91	0.48	10.13	1.41	2.15	trace	1.13	0.21	4.50	1.85	0.44 = 100.06
74.24	12.13	2.38	—	—	0.90	0.19	6.68	2.56	0.04	100.00

For Benrath's experiments on the manufacture of glass by fusing mixtures of this rock with limestone, see *Dingl. pol. J.* cxv. 264; *Jahresb. f. Chem.* 1870, 1160.

REDONDITE. A phosphate from the island of Redondas, West Indies. It is amorphous, resembles allophane, but is sometimes translucent, from porosity, to opaque; greenish to yellowish white, rarely with milk-white spots. Fracture conchoidal to earthy; the earthy varieties adhere strongly to the tongue. Hardness 3·5 to 4. Sp. gr. 1·90–2·07. The mineral contains, in addition to traces of SO_3 , Na, Cl and Mg:

P_2O_5	Fe_2O_3	Al_2O_3	H_2O	SiO_2	CaO
43·20	14·40	16·60	24·00	1·60	0·67 = 100·37

(C. U. Shepard, *Sill. Am. J.* [2], xlvii. 428). Another specimen gave sp. gr. = 2·019, perhaps too high on account of admixed silica (8·8 p.c.); it contained 24·73 p.c. water and 40·19 P_2O_5 , or, after making the necessary allowance for impurities, 44·07 (*ibid.* 1. 06).

REFRACTION. See LIGHT (p. 741).

REGIANIN. A substance obtained from the green shell of the walnut (*Juglans regia*). It may be extracted by benzene, and crystallises in yellowish elongated octohedrons or feathery groups of prisms. It is easily decomposable, and forms, with the fixed alkalis and ammonia, solutions of a fine purple-red colour, from which acids throw down brown flocks. By redissolving these in weak soda-ley, precipitating with hydrochloric acid, and washing with boiling water, regianic acid, $\text{C}^8\text{H}^6\text{O}_7$, is obtained as a dense amorphous pitch-black powder insoluble in water, soluble with purple-red colour in alkalis. It forms a brown lead salt, $\text{PbO}, \text{C}^8\text{H}^6\text{O}_7$, a pitch-black silver salt, and a flesh-coloured lime salt, which is precipitated by boiling its solution with a small quantity of ammonia (Philpson, *Chem. News*, xxiv. 119).

REISSITE. A zeolitic mineral occurring, together with quartz and desmin, in a trachytic conglomerate on Thera (Santorin), in short prismatic crystals belonging to the rhombic system. It is transparent and colourless, or whitish with a vitreous lustre, melts easily, dissolves after heating more easily than before, with separation of a jelly. The solution contains lime and alkalis (K. v. Fritzsche, *Jahrb. f. Mineralogie*, 1870, 80). According to Hesseberg's measurements (*ibid.* 480), the crystals exhibit the combination $\infty \text{P} : \infty \text{P} \infty : 2\text{P}2$. Angle $\infty \text{P} : \infty \text{P} = 134^\circ 8'$. Cleavage parallel to the brachydiagonal.

RESINS, FOSSIL. H. Spirgatis (*N. Rep. Pharm.* xx. 321) has examined a fossil resin from the coast of the Baltic, near Brusterort. It is commonly known as 'unripe amber,' but differs essentially from amber by the absence of succinic acid; on the other hand, it exhibits several points of resemblance to Krantzite (iii. 448). It is inodorous, light yellow or greenish, nearly transparent, but covered with a thin opaque crust. When heated it burns with a bright smoky flame, leaving 0·33 p.c. ash. It becomes darker at 100° , and melts above 300° . Sp. gr. = 0·934. Analysis gave 86·02 p.c. carbon, and 10·93 hydrogen, agreeing with the formula, $\text{C}^{10}\text{H}^{12}\text{O}$, which requires 86·02 C, 11·11 H, and 2·87 O.

Rosthornite (H. Hüfer, *Jahrb. f. Mineralogie*, 1871, 561). This resin occurs in the coal-beds of the Sonnberg, near Guttaring in Carinthia. It has a fatty lustre, a brown colour with garnet glimmer, wine-yellow by transmitted light, especially in splinters, and a light-brown to orange-yellow streak. It is brittle and may be scratched with the nail. Sp. gr. = 1·076. When heated in the air, it gives off white vapours having an aromatic odour, and burns with a deep yellow smoky flame, without leaving any residue. At 96° it begins to melt to a viscid, brown-red mass, which throws up bubbles at 160° , and emits white vapours from 215° to 225° , at which latter temperature the mass becomes mobile, assumes a dark purple-red colour, and emits a fetid gaseous mixture, but does not give off succinic acid. When fused with alkaline carbonates, it does not exhibit any trace of sulphur, although that element is present in the coal in the immediate neighbourhood of the resin. Rosthornite is not altered by dilute nitric acid, by potash-ley, or by alcohol, either in the cold or on boiling; in warm ether, however, it dissolves partially, forming a turbid wine-yellow solution, and leaving a white tumefied residue. In cold turpentine-oil it remains unaltered, but hot turpentine-oil dissolves the pure resin almost entirely, leaving only a small quantity of dark-coloured matter (enclosed particles of coal). It swells slightly in cold and dissolves partially in hot petroleum. In benzene it dissolves at ordinary temperatures, forming a clear dark wine-yellow liquid.

Rosthornite in its physical characters bears considerable resemblance to jaulingite and pyroretin, but in chemical composition it approaches more nearly to euosmite, and still more to the fossil resin of Girona, near Bucaramanga in New Granada, as will be seen from the following comparison:—

	Rosthornite	Janlingite	Eucemite	Girona resin
Carbon . .	84.42	74.43	81.89	82.7
Hydrogen . .	11.01	9.04	11.73	10.8
Oxygen . .	4.57	16.53	6.38	6.5
	100.00	100.00	100.00	100.0

Eucemite is distinguished from rosthornite by its strong odour of camphor and rosemary, by its easy and complete solubility in alcohol and ether, and by the deep yellow colour which it imparts to potash-ley, &c. Pyroretin also differs from rosthornite in its behaviour to solvents, and moreover contains 10 p.c. oxygen. Girona or Bucaramanga resin, which occurs in auriferous porphyritic alluvians, resembles rosthornite in its behaviour to alcohol and ether, but is transparent, pale yellow, and very much like amber in its physical characters.

Rosthornite, therefore, cannot be included either physically or chemically in the succinite group, or in that of retinite (80.4 C; 10.7 H; 8.7 O), neither on chemical grounds can it be referred to the ixolite group, to which janlingite belongs. It appears rather to form a type of solid resins rich in carbon and poor in oxygen.

Fossil Resin from the Val d'Arno Superiore (I. Guaraschi, *Cimento*, v.-vi. 175). The lignites of the Figliano basin on the left bank of the Arno contain several fossil resins, one of which is called by the country people 'combustibile earth' (*terra che bruccia*). This resin is a light, very friable, amorphous, yellowish-white mass, which burns like touchwood, and with a somewhat smoky flame. It contains 41.3 p.c. organic and 58.7 mineral substance, the latter consisting of silica, ferric oxide, alumina, manganese oxide (trace), lime, magnesia, potash and soda, soluble in hydrochloric acid; and silica, iron silicate, and aluminium silicate, insoluble in that acid.

The organic matter is almost wholly soluble in alcohol, and may be resolved, by fractional solution in that liquid, into two resins, α and β , having the following composition:—

	O	H	O
Resin α	72.72	9.41	17.87 = 100
Resin β	76.94	9.12	13.94 = 100

The composition of α agrees nearly with the formula $C^{40}H^{14}O^8$, that of β with $C^{40}H^{13}O^8$. The resin α may be supposed to have been formed by oxidation of a polymeride of turpentine-oil, $4C^{10}H^{14} + O^8 = C^{40}H^{14}O^8$, and β by abstraction of the elements of water from α : $C^{40}H^{14}O^8 - 3H^2O = C^{40}H^{13}O^8$. Both exhibit considerable analogy, both geologically and chemically, to the group of resins called *pyropissite*, from the lignite of Weissenfels (iv. 769).

Resin α is blackish when melted, yellowish in powder, lighter than water, softens at 75°, and melts completely at 90°. It dissolves with brown colour in alcohol, very easily in benzene and in turpentine-oil, very slightly in ether. Strong sulphuric acid dissolves it in the cold, more easily when heated. Nitric acid acts but slowly, or not at all, upon the resin itself; but when added to the sulphuric acid solution it appears to form a nitro-substitution product. By melting the resin with potash, no organic acid is formed, but merely an alkaline carbonate. By distillation the resin yields a brown empyreumatic liquid which does not appear to contain succinic acid.

Resin β is blackish and amorphous, very slightly soluble in alcohol, much more freely in benzene and turpentine-oil. It is lighter than water, melts at a temperature above 120°, and is soluble in potash.

RESORCIN, $C^6H^4O^2 = C^6H^4(HO)^2$. This modification of dioxybenzene, formerly regarded as a para-compound, is now placed in the meta or isophthalic series (see *Pyrozois*, p. 924).

Resorcin is formed by the dry distillation of brazilin (p. 208), and may be easily prepared by mixing the wash- and mother-waters obtained in the manufacture of brazilin from Brazil-wood extract, with chalk, evaporating to dryness, and subjecting the residue to dry distillation. This, according to E. Kopp, is the easiest and cheapest of all methods of preparing resorcin.

Resorcin melts at 98°–99° and distils at 266°–267°. A very characteristic test for it is to treat a small quantity with *fuming sulphuric acid*, which dissolves it with an orange-yellow colour, gradually darkening and changing in 20–30 minutes to greenish-blue, and ultimately to a pure blue: on warming the liquid to 90°–100° this blue changes to a fine purple-red (E. Kopp, *Deut. Chem. Ges. Ber.* vi. 446).

A mixture of resorcin with *furfural*, touched with a drop of hydrochloric acid, forms an indigo-blue substance which dissolves with green colour in water, and is precipitated by hydrochloric acid in blue flocks (A. Baeyer, *Deut. Chem. Ges. Ber.* v. 25).

Benzoin aldehyde reacts with resorcin in the same way as with pyrogallol (p. 1031).

Resorcin heated to 195° with *phthalic anhydride* yields resophthalcin or fluorescein, $C^{12}H^{10}O^3 = 2C^6H^4O^2 + C^6H^4O^2 - 2H^2O$ (p. 524). Heated with *succinic anhydride*, it yields a yellow, resinous substance, similar in character to fluorescein, and doubtless consisting of the succinein of resorcin, $C^{12}H^{10}O^3 = 2C^6H^4O^2 + C^6H^4O^2 - 2H^2O$. Heated with *oxalic* and *sulphuric acids*, it yields a yellow substance, which differs from the phthalcin and succinein just mentioned in forming a non-fluorescent solution, and appears to be identical with euxanthone (1st *Suppl.* 610), which may accordingly be regarded as the carbonein of resorcin:

(Baeyer, *Deut. Chem. Ges. Ber.* iv. 682).

Azo-derivatives of Resorcin (Weselsky, *Deut. Chem. Ges. Ber.* iv. 613). *Diazo-resorcin*, $C^{12}H^{12}N^2O^4$, is formed by the action of nitrous acid on an ethereal solution of resorcin:

It forms brown granular crystals, with a green metallic lustre; is sparingly soluble in water, dissolves more freely in alcohol and acetic acid, with a dark cherry-red colour, and its alkaline solutions have a splendid blue-violet colour. By the action of strong sulphuric or hydrochloric acid it is converted into diazo-resorufin, $C^{12}H^{10}N^2O^4$, which separates from the hydrochloric acid solution in small, dark red, granular crystals. It is nearly insoluble in water, alcohol and ether; concentrated sulphuric acid dissolves it with a crimson colour, and the same colour is exhibited by its alkaline solutions, which have also a beautiful vermilion-red fluorescence.

When diazo-resorcin is heated with tin and strong hydrochloric acid, the solution assumes an emerald-green colour, and on cooling, hydro-diazo-resorufin hydrochloride, $C^{12}H^{12}N^2O^4.H^2 + 3HCl$, crystallises out in the form of green leaflets with a silvery lustre, or of light green needles. The crystals, when exposed to the air, assume the colour and the coppery lustre of indigo. On heating this compound in a current of air, the hydrochloric acid escapes, and oxidation takes place, diazo-resorufin being reproduced. When a solution of the hydrochloride is heated with diazo-resorufin, a dark-blue solution is obtained, from which dark bottle-green, shining needles crystallise out, which are a combination of the two substances, analogous to quinchidrone.

By heating diazo-resorcin with acetyl chloride in closed tubes, dehydro-diazo-resorcin hydrochloride is formed:

It crystallises in yellow scales, resembling mosaic gold, insoluble in water but soluble in alcohol with a straw colour, and in alkalis with a magnificent violet. By cold nitric acid it is converted into a brick-red flocculent body, which, when treated with warm nitric acid, gives purple plates, the alcoholic or ethereal solution of which shows a remarkable vermilion-red fluorescence. Both compounds are true colouring matters, and the former has the property that the fluorescence of its ammoniacal solution appears also on silk dyed with it. The above reaction of acetyl chloride also gives rise to acetyl-diazo-resorcin, in the form of an amber-yellow resin.

By heating diazo-resorcin with strong nitric acid tetrazo-resorcin nitrate, $C^{12}H^8N^4O^6.(NO^3)^2$, is obtained:

1. $C^{12}H^{12}N^2O^3 + N^2O^3 = 3H^2O + C^{12}H^8N^4O^6$
2. $C^{12}H^8N^4O^6 + 3N^2O^3 = 3NO^2 + C^{12}H^8N^4O^6.(NO^3)^2$

This nitrate crystallises in well-defined garnet-red needles, which have a brilliant metallic lustre, dissolve in water and alcohol, and very readily in ether with a pure indigo-blue colour. By further action of nitric acid, tetrazo-resorufin nitrate, $C^{12}H^8N^4O^6.(NO^3)^2$, is formed. The crystals contain water, have the appearance of potassium permanganate, and dissolve with the same colour in water, alcohol, and ether. On drying, the water of crystallisation escapes, and a dull, brick-red powder is left behind. On boiling it with water, decomposition takes place, which is accelerated in presence of alkalis; from the brown solution dark flakes separate out. By the action of nascent hydrogen, it is transformed into dihydro-tetrazo-resorufin nitrate, $C^{12}H^{10}N^4O^6.H^2.(NO^3)^2$, which crystallises from its cherry-red alcoholic solution in small needles.

2nd *Sup.*

Hydroamido-tetrazo-resorufin, $C^{17}H^{22}N^4O^3 \cdot 6NH^2 \cdot 9HCl$ is the final product obtained by heating any of the above tetrazo-compounds with tin and hydrochloric acid. It crystallises in long, colourless needles, which, on exposure to the air, assume a rose colour; in alkalis it dissolves with a blue colour. By passing air through the ammoniacal solution, it becomes brown, whilst green crystals, with a cantharidic reflection, separate out. This body is *hydro-imido-tetrazo-resorufin*, $C^{16}H^{22}N^4O^3(NH)^2$; it is insoluble in water, and dissolves in concentrated hydrochloric and diluted nitric acid, with a wine-red colour.

Bromoresorcins. *Pentabromoresorcin*, $C^6HBr^5O^2$, is prepared by adding an aqueous solution of resorcin, with constant agitation, to a cooled mixture of bromine and water (in the proportion of about 5 : 1). By two or three crystallisations from carbon sulphide it is obtained pure in large colourless or sulphur-yellow prisms. It melts at 113.5° , is nearly insoluble in water, dissolves easily in ether and in alcohol, moderately in benzene. From solution in hot petroleum oil it separates for the most part on cooling. *Hydriodic acid* converts it into a compound which crystallises in colourless needles; probably tribromoresorcin (Stenhouse, *Ann. Ch. Pharm.* clixiii. 182).

The composition of pentabromoresorcin appears to be at variance with Kekulé's theory of the constitution of the dioxybenzenes, $C^6H^2O^2$, according to which one of the five hydrogen atoms which are replaced by bromine to form the compound, $C^6HBr^5O^2$, should exist in the form of hydroxyl, and should therefore not be thus replaceable. This difficulty suggested to Liebermann a. Dittler (*Deut. Chem. Ges. Ber.* v. 1090) the idea that the compound in question might be really an addition-product, $C^6H^2Br^5O^2 \cdot Br^2$, containing 2 at. hydrogen more than are assigned to it by Stenhouse. To decide this point they determined the quantity of bromine required for its formation, and the quantity of hydrobromic acid evolved thereby. The result showed, however, that the reaction takes place exactly as stated by Stenhouse, that is to say, according to the equation:

and not as represented by the equation:

Liebermann a. Dittler also find that pentabromoresorcin heated to 150° – 160° gives off 2 at. bromine according to the equation:

leaving a substance which, after washing with ether to remove a little resinous matter, forms a crystalline powder having the composition $C^6HBr^3O^2$. This body may be regarded as tribromoresorcin-quinone:

and pentabromoresorcin may then be regarded as the additive compound:

It is, however, quite possible that tribromoresorcin-quinone may be derived from a pentabromoresorcin having the constitution $C^6HBr^3 \begin{array}{c} \diagup OBr \\ \diagdown OBr \end{array}$.

Chlororesorcins. *Pentachlororesorcin*, $C^6HCl^5O^2$, is best prepared by adding alternately in small portions 5 pts. potassium chlorate and a solution of 2 pts. resorcin in 8 pts. hydrochloric acid to 40 pts. of hydrochloric acid, keeping the potassium chlorate always in excess, and cooling the mixture to prevent too great a rise of temperature. The crude product which separates on leaving the liquid at rest, appears to consist mainly of a hydrate of chlororesorcin; for on heating it with a small quantity of carbon sulphide, and filtering the solution quickly, small white crystalline scales separate out, which are but sparingly soluble in carbon sulphide; and on distilling the carbon sulphide solution, water passes over, and the concentrated liquid now deposits anhydrous pentachlororesorcin in shining colourless prisms or thin prisms. By one or two re-crystallisations it may be obtained pure. It melts at 92.5° is moderately soluble in hot water, and separates therefrom on cooling, evidently a hydrate, in the form of a white, opaque mass, in which no crystals can be detected.

recognised. It dissolves easily in carbon sulphide, benzene and petroleum-oil, still more easily in alcohol and ether (Stenhouse, *Ann. Ch. Pharm.* clxiii. 182; *Proc. Roy. Soc.* xx. 78).

Pentachlororesorcin is converted by hydriodic acid into a crystalline compound, which appears to be trichlororesorcin (Stenhouse, *Chem. News*, xxiii. 230).

Iodoresorcin, $C^6H^3IO^2$, is prepared by agitating an ethereal solution containing 1 mol. resorcin to 1 mol. iodine, with dry precipitated mercuric oxide, or better with litharge, then distilling off the ether, and exhausting the residue with hot benzene. Iodoresorcin then separates on cooling in the crystalline state, and may be purified by two or three alternate crystallisations from benzene and hot water. It is a colourless, crystalline body, resembling iodorein (p. 879) in its general characters, but much more soluble in water (Stenhouse, *Chem. News*, xxvi. 179).

Nitroresorcins. *Mononitroresorcin*, $C^6H^3(NO^2)O^2$, is contained in considerable quantity in the ethereal mother-liquors obtained in the preparation of diazo-resorcin. To separate it, the resinous residue is boiled with water, and the filtered solution mixed with lead acetate, whereby a dirty-brown precipitate is formed. From the filtrate from this precipitate, the excess of lead is removed by sulphuric acid, and the yellow liquid is shaken up with ether, which, on evaporating, leaves the crude nitroresorcin as a crystalline mass. This is pressed and dissolved in water, and the solution is saturated with baryta-water and left to cool, whereupon the neutral barium salt of nitroresorcin crystallises out in long needles. The solution of this salt, decomposed by sulphuric acid, is exhausted by ether, and the residue left when the ether evaporates is purified by recrystallisation from hot water.

Mononitroresorcin crystallises from hot water or from alcohol in long capillary, folded, thread-like, lemon-yellow needles, which do not taste bitter, are not explosive, and cannot be sublimed without decomposition. Its melting point is 115° . In hot water it melts to an oil before dissolving.

The neutral *barium compound*, $C^6H^3(NO^2)O^2Ba + 5H^2O$, crystallises from hot water in tufts of needles, often half an inch long, and having the colour of potassium dichromate. By slow separation from more dilute solutions, thicker prisms are obtained, having the aspect of potassium ferricyanide, and a bluish metallic lustre. According to Ditscheiner's measurements, they very probably belong to the triclinic system. Combination: $\infty P' : \infty P' : \infty P' \infty : P' \infty : P' \infty$. Angle $\infty P' : \infty P' = 117^\circ 30'$; $\infty P' : \infty P'$ right behind = $129^\circ 50'$; $\infty P' : \infty P' = 50^\circ$; $\infty P' : \infty P' = 111^\circ 50'$. The faces $P' \infty$ and $P' \infty$ are deeply striated.

The *monobasic barium compound*, $[C^6H^3(NO^2)(OH)O]^2Ba + H^2O$, is obtained by passing carbon dioxide into the hot solution of the preceding salt. It crystallises in drusy aggregates of dark yellow, slender needles, which are more soluble in water than the preceding salt.

An *acid barium compound* represented by the formula:

separates from a solution of the neutral salt mixed with acetic acid, in golden-yellow, moderately long, shining, brittle needles, arranged in tufts or stellate groups. It may also be prepared by dividing the hot solution of a weighed quantity of mononitroresorcin into two equal parts, saturating one with barium carbonate and then adding the other. The *potassium salt*, obtained by decomposing the neutral barium salt with potassium sulphate, forms orange-red flat needles, easily soluble in water. The *magnesium salt*, prepared in like manner from the neutral barium salt, crystallises in orange-red, long, capillary, felted needles, somewhat more soluble than the corresponding barium salt (Weselsky, *Ann. Ch. Pharm.* clxiv. 1).

Dibromonitroresorcin, $CHBr^2(NO^2)(OH)^2$, is obtained by dropping bromine into an ethereal solution of nitroresorcin till the colour no longer disappears, evaporating the ether, and crystallising the residue from alcohol, in yellow laminae resembling iodide of lead. It is also formed by the action of nitric acid containing nitrous acid on an ethereal solution of tribromoresorcin. It melts at 147° . The *barium compound*, $[CHBr^2(NO^2)(OH)O]^2Ba + 4H^2O$, forms small orange-red needles, which have a blue reflex, and are very slightly soluble in water (Weselsky).

Trinitroresorcin. *Oxypticic* or *Styptic acid*, $C^6H^3(NO^2)O^2$.—This compound may be prepared in the same way as trinitroresorcin (p. 879). It crystallises in light yellow laminae melting at 175.5° , dissolves in 156 pts. water at 14° , and is precipitated from this solution by stronger acids, even when added in very small quantity. Its

barium salt, $C^6H(NO^2)_2O^2Ba + 3H^2O$, forms small, light yellow, rhombic laminae, more soluble in water than the corresponding orcin compound; gives off its water when heated a little above 100° , and explodes with great violence at a higher temperature. The *lead salt* crystallises from hot aqueous solution, in dark, yellow needles; it is slightly soluble in water, easily soluble in acetic acid, and is precipitated from this solution by alcohol. The *silver salt*, $C^6H(NO^2)_2O^2Ag^2$, crystallises from hot water in long, slender, yellowish-brown needles (Stenhouse, *Proc. Roy. Soc.* xix. 410).

RESORCIN-CARBONIZIN, $C^6H^2O^4 = 2C^6H^2O^3 + CO - 2H^2O$ (see p. 1041).

RESORCIN-INDOPHANE, $C^6H^2N^2O^4$. This name is given by J. Schroder (*Ann. Ch. Pharm.* cxliii. 297) to an acid compound, the potassium-salt of which is obtained by the action of potassium cyanide on the potassium salt of trinitroresorcin (potassium styphnate). To prepare this salt, a solution of 20 grams potassium cyanide in 100 c.c. water at 40° - 50° is gradually added to a solution of 100 grams of potassium styphnate in a litre of water, heated to 70° - 80° ; the heat is continued for 10-15 minutes longer; the liquid quickly filtered through linen; and the separated salt is washed with cold water till the wash-water begins to show a green colour, and then pressed. The filtrate contains a large quantity of potassium nitrite. On adding dilute sulphuric acid to the warm concentrated dark green solution, crude resorcin-indophane separates on cooling in slender needles. For further purification, the pressed crystalline mass is redissolved in boiling water, and the filtered solution is mixed with strong hydrochloric acid, whereby the resorcin-indophane, which cannot be recrystallised from water, is reprecipitated.

Resorcin-indophane thus prepared forms small, anhydrous needles, which exhibit very distinct forms under the microscope, and have a lustre of bronze, changed to that of copper by friction. It dissolves easily, even in cold water, with pure blue-violet colour, is insoluble in alcohol and ether, and is dissolved in not inconsiderable quantity by hot concentrated acetic acid. It likewise dissolves, without decomposition, in cold concentrated sulphuric acid, and is precipitated from the solution by water. When heated in the air, it burns away with slight detonation. Nitric acid converts it into a yellow syrup in which crystals of oxalic acid form on standing. The blue solution of resorcin-indophane is decolorised by *chlorine-water*, and the resulting wine-yellow liquid yields to ether a product which, as the ether evaporates, remains as a resin having the pungent odour of chloropierin.

Resorcin-indophane appears to be completely decomposed by melting *potash*. On heating it with *sodium-anaglam*, the insoluble sodium salt is immediately produced, on which the evolved hydrogen exerts no action. In like manner, on treating it with *tin* and *hydrochloric acid*, the only product is a tin compound, very difficult to purify, and apparently consisting for the most part of the unaltered substance. Resorcin-indophane is not attacked by *acetyl chloride*. When heated with *soda-lime* it gives off only three-fourths of its nitrogen as ammonia, showing that one atom of nitrogen must be contained in it as NO^2 .

Potassium Resorcin-indophane, $C^6H^2K^2N^2O^6 + H^2O$, crystallises in microscopic needles. After pressing and drying it forms a black-brown mass, acquiring metallic lustre by friction. It dissolves with difficulty in cold water, but completely in boiling water, the solution having a pure green colour like that of alkaline manganates. It cannot be recrystallised from water, for the hot concentrated solution solidifies to a jelly on cooling. On adding *potash* to the solution, the salt separates in its original form. It is quite insoluble in alcohol. On mixing a solution of pure resorcin-indophane with a solution of pure potassium carbonate, a dark flocculent amorphous precipitate is formed, which, after washing with water containing a trace of alkali, dries up to a hard dark-coloured mass, having a green metallic lustre. The water of crystallisation is not given off till the salt is raised to a temperature at which it decomposes with explosion. The *sodium salt*, $C^6H^2Na^2N^2O^6 + H^2O$, is analogous in properties to the potassium salt. The *barium salt*, $C^6H^2Ba^2N^2O^6 + H^2O$, separates as a dark-coloured precipitate on mixing the solution of the sodium salt with barium chloride.

RESORCIN-PHTHALIN, $C^{12}H^{10}O^3 = 2C^6H^2O^3 + C^6H^2O^3 - 2H^2O$. Syn. with *FLUORESCIN* (p. 524).

RESORCIN-SUCOXININ, $C^6H^2O^3 = 2C^6H^2O^3 + C^6H^2O^3 - 2H^2O$ (p. 1041).

RESPIRATION. As far as the chemistry of respiration is concerned, the most important points which remain to be settled are those relating to the so-called 'internal respiration,' and much attention has lately been given to this point. We are, however, still much in the dark as to the substances mainly oxidised in various tissues, and as to the stages of oxidation attained in each; and, in fact, it is yet far from settled.

nately settled how much of the oxidation of the body goes on in the blood itself, and how much in the tissues outside the blood-vessels.

Ester and St. Pierre found that blood obtained from arteries distant from the heart contained much less loose oxygen than blood drawn from arteries nearer to it, and they concluded that the difference was due to great oxidation going on in the arterial blood itself. Both Hirschmann and Pflüger (*Arch. f. d. Gesam. Phys.* 1868) maintain, however, that the difference in loose oxygen which the above observers found does not exist: the latter observer could find no constant difference in the quantity of loose oxygen in the blood of the femoral and carotid arteries of the dog; and Hoppe-Seyler, who finds some difference, makes it much less than Ester and St. Pierre supposed, and believes it due to the action of the arterial walls, and not to reducing matters in the blood itself. On the other hand, Pflüger (*Centralb. f. d. Med. Wiss.* 1867, No. 46) has shown that blood, after removal from the body, very rapidly fixes some of its loose oxygen, and this at first sight would seem to point to a normal rapid oxidation going on in the circulating blood. Using improved methods which enabled him to extract the gases from fresh-drawn blood very rapidly, he found that all the previous estimations of them were erroneous, the oxygen being given too low, and the carbonic anhydride too high; the average quantity of oxygen which he finds in the arterial blood of the dog is 16.0 vols. in 100 vols. of blood, the gas being calculated at 0° C. and 1 M. mercury pressure (= 22-23 vols. at 760 mm). A. Schmidt gets almost exactly the same average quantity. The extremely small difference, if any, as regards its gases, which, as mentioned above, Pflüger has found to exist between blood taken from arteries near the heart, and that from those more distant from it, appears to show that this oxidation, which goes on so rapidly in blood removed from the body, does not go on at anything like the same rate in the circulating blood; the process is probably almost entirely *post mortem*, and due to that partial decomposition of the hæmoglobin which is known to occur in blood exposed to a vacuum, with formation of products which rapidly combine with oxygen. Stale blood (in which the hæmoglobin is partially decomposed), after saturation with oxygen, very rapidly becomes again venous, while fresh blood, left to itself, does so comparatively slowly; this goes to show that the hæmoglobin products are powerful reducing agents, and Pflüger and Zuntz have also proved that the addition of acids (as phosphoric and tartaric), which Preyer found to diminish the quantity of loose oxygen in blood, does so only when they are added in such quantity as to decompose the hæmoglobin, and that, after it has been all broken up, the further addition of acid is without effect. Maintaining the view that oxidation goes on mainly in the tissues around and not in the blood itself, Pflüger points out also (*Arch. f. d. Ges. Phys.* 1872, vi.) that, from what we know of the laws of gaseous diffusion, oxygen must pass, as such, from the blood into the neighbouring tissues, and carbonic anhydride in the opposite direction, and he shows that even asphyxiated blood, if it be examined quite fresh, contains an extremely small amount of reducing matters. In reference to this question Preyer has pointed out that it is almost certain that uncombined oxygen passes in the placenta from the maternal blood through the vascular walls into the foetal blood, and if such a passage of uncombined oxygen occurs in this tissue, there can be no doubt that it takes place in others also. Putting these facts together, it seems probable that most of the oxidation going on in the body occurs outside blood-vessels; but as to the rate at which it occurs in different tissues, or as to the stages of oxidation attained in each, we know but little. Bert (*Leçons sur la Phys. de la Resp.*, Paris, 1870) found that equal weights of different tissues, taken from an animal bled to death, took up different quantities of oxygen from blood. Arranged in order, beginning with those which take up most, the series runs—muscle, brain, kidney, spleen, testicle, and bone. A. Schmidt found that blood sent repeatedly through the vessels of fresh kidneys, kept at the body temperature, lost very rapidly nearly all its loosely held oxygen; no urine was secreted.

As to the matters which are burnt in the small oxidation which goes on normally in the blood almost as little is known. Beaumark compared the quantity of fat in blood, before it had passed through the lungs, with that in blood after passing through those organs: he found 0.1803 p.c. in the former, and 0.0062 p.c. in the latter, which also contained little or no fluid fats, while the former contained a considerable portion of them; from this he concludes that the fluid fats of the blood are oxidised in their circulation through the lungs. Schemenetjewski also (*Zeitschr. f. Biologie*, 1868, Dec.) has investigated the effect on the respiratory gases of the injection of combustible non-nitrogenated matters into the blood; he found that sodic lactate or caproate increased the quantity of oxygen taken up in the lungs and the quantity of carbonic anhydride given out, and J. J. Müller obtained the same results. Glycerin acted similarly but more rapidly, while sodic acetate and formate were without effect; grape-sugar sometimes increased the respiratory gas exchanges, but sometimes not, from which he concludes that it is not oxidised, as such, in the blood. It does not

indeed appear at all certain that any of these matters were oxidised in the blood itself.

With respect to the carbonic anhydride of the blood, considerable modifications will have to be introduced into the views which have hitherto prevailed, both as to its origin and state of combination. Until recently it has been very generally assumed, that it was contained wholly in the plasma and, in it, existed in three conditions, viz. dissolved simply, feebly combined, in the form of a double salt, with phosphate (Fernet's salt), and stably combined in the form of normal carbonates. Preyer (*Centr. f. d. Med. Wissen.* 1866) found that alkaline fluids, such as solutions of sodic carbonate or phosphate, or blood serum, or the urine of herbivora, all become acid or neutral when treated with carbonic anhydride, before such a quantity of the gas was added to them as to cause some of it to be simply in solution in the fluid; from this he concludes that the alkaline circulating blood can contain no simply dissolved carbonic anhydride, especially as it is known that fresh blood can combine with CO_2 when exposed to it; he believes that those phenomena presented in the vacuum by blood, which have been taken to prove that it contains free CO_2 , are really due to the development of acids by the decomposition of the hæmoglobin, which acids turn out carbonic anhydride from some of its compounds. In connection with this point Schöffer, Zuntz, and others have shown that an acid does not develop in the blood when it is removed from the body, and that its development is dependent on the presence of the red blood corpuscles. Now, if no free carbonic anhydride exists in the circulating blood, this must modify the view that another portion of this gas is combined in it in the form of Fernet's salt; for, as Hermann has shown, this salt can only exist in the presence of a certain tension of CO_2 , which would not be exerted if none of it were present in the blood in an uncombined state; either, then, some carbonic anhydride exists in the blood in simple solution, or the view that a good deal of it is held in the form of Fernet's salt is incorrect. Hermann inclines to the former opinion, but there is a good deal of evidence tending to show that the latter is the correct one. Sertoli (*Centr. f. d. Med. Wissen.* 1868, and *Med. Chem. Unters. v. Hoppe-Seyler*, 3 Heft.) found that the quantity of sodic phosphate which exists in the blood of oxen is extremely small. Laying aside the quantity of phosphoric acid which is combined with calcium in the blood, he found that almost all the rest, which had been previously considered as combined in the form of sodic phosphate, really belonged to the lecithin of the serum, which had been neglected by former observers; estimating the sodic phosphate as high as possible, he found that the quantity of carbonic anhydride which it could hold as Fernet's salt was not more than 0.75 vol. in 100 vols. of blood. The observations of other observers have at the same time shown that the red blood corpuscles are capable of combining with carbonic anhydride. Schmidt (1 *Abth. d. K. Sachs. Gesell.* 1867, and *Centr. f. d. Med. Wissen.* 1867) found that a part of the carbonic anhydride of the blood was stably combined with some body in the corpuscles, but that the quantity so combined was very variable, and greatly dependent on the amount of the gas obtainable from the plasma by the air-pump, and Zuntz, who has investigated the matter more thoroughly, confirms this (*Centr. f. d. Med. Wissen.* 1867, and *Beiträge 2 Phys. d. Blutes*, Bonn. 1868). He found that drawn blood exposed to a partial pressure of 8 p.c. of CO_2 took up about its normal quantity of carbonic anhydride; under 10 p.c. partial pressure, the quantity taken up was disproportionately increased, and the excess was mainly held chemically bound by the corpuscles; which he therefore concludes to contain a body (perhaps the alkali-hæmoglobin of Pflüger) which is capable, under different partial pressures of carbonic anhydride, of combining with different quantities of that gas; under a partial pressure = 8 mm. of mercury, he finds the CO_2 of the blood only to exist in the plasma (*Berl. Klin. Wochenschrift*, 1870, 186). From the mean of three analyses of the gases of normal blood, he concludes that 92 p.c. of its carbonic anhydride is chemically combined, 35.5 p.c. in the plasma, and 56.5 p.c. in the corpuscles. From Wolffburg's experiments (*Arch. f. d. Ges. Phys.* 1871 and 1872) it appears also that the tension of the carbonic anhydride in venous blood and in the air-cells of the lungs has been previously reckoned too high; he makes it equal to that in a gaseous mixture containing 3.6 p.c. of the gas, if this lower tension in the air-cells be correct, and if a great part of the carbonic anhydride of the blood exists in combination in the corpuscles, it becomes more easy than before to understand how the taking up of oxygen and the formation of ox hæmoglobin in the corpuscles during the pulmonary circulation is able to turn combined carbonic anhydride there into free, and so raise the tension of the gas sufficiently to enable it to diffuse into the air-cells in spite of the percentage of the gas in the air which they contain.

With regard to the source of the carbonic anhydride which is found in the blood, it is probable that a great part of it is not nearly so directly the result of oxidation as has been more or less definitely believed, but that a portion of it arises from the breaking up of more complex molecules without any necessary simultaneous oxidation;

such a process certainly appears to occur in the muscles (see *MUSCULAR TISSUE*), and J. J. Muller (*Bericht d. K. Sachs. Gesell. Wiss.* 1869) repeating, in a modified form, Schömann's experiments with sodic lactate, referred to above, finds that its introduction into the blood increases the quantity of carbonic anhydride expired, quite out of proportion to the extra quantity of oxygen taken up at the same time; he concludes that the lactate is not simply oxidised in the blood, but is broken up there, carbonic anhydride being one of the products. The origin of carbonic anhydride from such sources as these probably is the reason of the great difference between day and night with respect to the oxygen taken up and the carbonic anhydride given out during each, which Pettekofer and Voit found to exist. During the day the greater amount of muscular work going on develops a large amount of carbonic anhydride in the body, and so raises disproportionately the amount of the gas given off, as compared with night, when much less muscular work occurs, and more oxygen is taken up by the lungs than is expired in the carbonic anhydride. Liebermeister (*Arch. f. Klin. Med.* 1869. vii.) has also shown that the difference pointed out by Pettekofer & Voit is greatly dependent on the time of feeding.

Bert (*Compt. rend.* 1872) has made observations upon the effect of different atmospheric pressures on respiration; he found that birds breathing air under a pressure of 20 atmospheres died with convulsions and other symptoms, which he considers are due to oxygen poisoning; for if the pressure after these atmospheres was raised by nitrogen only, these symptoms did not appear. Rapid diminution of the pressure from seven atmospheres to one, killed animals either immediately or after a day or two, gases being set free from the blood within the blood-vessels. Analysis of the gas so set free showed that it contained 70-90 p.c. of nitrogen, the rest being carbonic anhydride.

H. N. M.

RESTORMELITE. A hydrated aluminium silicate from Restormel in Cornwall, exhibiting the characters of a decomposition-product of felspar. It is greenish-grey, amorphous, with a conchoidal fracture, and resembles agmatolite in external appearance. When heated, it gives off water, and becomes grey and opaque. It does not gelatinise with sulphuric acid. Sp. gr. = 2.58. Hardness = 2. Its composition, according to the mean of six analyses, is:

SiO ²	Al ² O ³	FeO	MgO	K ² O	Na ² O	H ² O
45.66	35.09	1.18	0.85	2.30	4.39	11.68 = 101.15.

These numbers correspond pretty well with the formula of kaolinite, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 + 2\text{H}_2\text{O}$ (46.3 p.c. SiO_2 , 39.8 Al_2O_3 , 13.9 water), supposing the hydrogen to be partly replaced by sodium and potassium, and the aluminium by iron. Restormelite appears, however, to be an immature rather than an altered kaolinite (Church, *Chem. Soc. J.* [2], viii. 165).

RHAMNETIN. On the synthesis of this substance, the glucoside of rhamnetin, by boiling the lead-compound of rhamnetin with diacetyl-saccharose, see *GLUCOSIDES* (p. 567).

RHINANTHIN, $\text{C}_{20}\text{H}_{32}\text{O}_{10}$. This glucoside, which Ludwig obtained from the seeds of the common yellow rattle (*Rhinanthus Crista Galli*, 1st Suppl. 995), he has also prepared from those of *Alectrolophus hirsutus* (*Rhinanthus buccalis*, Wallroth). It crystallises in stellate groups of prisms; has a slightly bitter and nauseously sweet taste; dissolves easily in alcohol and in water. Its alcoholic solution mixed with hydrochloric acid, and heated, turns bluish-green, and decomposes. By dilute mineral acids it is resolved into a brown, non-crystallising substance called rhamnogenin, and a kind of sugar (H. Ludwig, *Arch. Pharm.* [2], cxlii. 199).

The seed of purple cow-wheat (*Melampyrum arvense*) yields to alcohol a chromo-glucoside, which in its reactions exhibits a close resemblance to rhinanthin (Ludwig & Müller, *ibid.* cxlii. 6).

ROSDINNE. The name given by Gladstone (*Chem. Soc. J.* [2], x. 3) to the hydrocarbon $\text{C}_{10}\text{H}_{18}$ from rosewood oil.

ROGADINE, $\text{C}_{17}\text{H}_{21}\text{NO}$ (1st Suppl. p. 995). This base may be regarded as dioxypapaverine (Hesse, *Ann. Ch. Pharm.* cliii. 47).

RICININE. According to E. Werner (*Chem. News*, xxii. 203) the constituent of castor-oil seeds, thus named by Tuson (v. 109) is not an alkaloid, but a magnesium salt having the composition $\text{C}_{18}\text{H}_{31}\text{O}_4 \cdot \text{Mg} + 6\text{H}_2\text{O}$. To this statement Tuson replies (*ibid.* 229) that the substance obtained by Werner is totally different from that designated by himself as ricinine, the latter containing 20.79 p.c. nitrogen and forming fine crystals.

RICINUS OIL. See CASTOR OIL (p. 270).

BIONITE. A bismuth fahl-ore occurring, together with heavy spar and quartz, at Cremenx in the Einfischthal (Val d'Anniviers) in the Canton Wallis. Analysis A is by Brauns, published by Petersen (*Jahrb. f. Mineralogie*, 1870, p. 464). The quantities of metal determined by this analysis require only 26.13 p.c. sulphur. Petersen himself found 26.87 sulphur, which he regards as too high, the excess arising from admixed copper-pyrites. Petersen therefore refers the analysis to the formula 3RS.RS^2 , which he regards as the typical formula of fahl-ores.

Petersen also gives an analysis (B), by R. Sontfer, of another bismuth fahl-ore from Neubulach in the Wurtemberg Schwarzwald. The mineral occurs in crude lumps, closely intergrown with the quartz matrix, one specimen only being crystallised in the combination $\frac{\text{O}}{2} \cdot \frac{2\text{O}_2}{2} \cdot \infty \text{O}$. Sp. gr. = 4.908.

S	As	Sb	Bi	Cu	Ag	Pb	Zn	Fe	Co	Ni	
29.10	11.44	2.19	13.07	37.52	0.04	—	—	6.51	1.20	—	= 101.07
24.85	13.63	4.28	6.33	41.43	trace	1.52	3.82	3.74	trace	trace	= 99.50

BITTINGERITE (v. 112, 1052). This mineral, from the Joachimsthal, has been re-examined by A. Schrauf (*Jahrb. f. Mineralogie*, 1872, 180). The small, many-faced monoclinic crystals are frequently twinned with the plane of combination parallel to 0P or $\infty \text{P}\infty$. Sp. gr. = 5.63. It contains 57.7 p.c. silver, together with arsenic and a little selenium, but no sulphur.

ROCKS. On the chemical character and composition of certain Cornish rocks, see KILLAS (p. 713).

On the Permian rocks of the Lower Odenwald, see E. Cohen (*Jahrb. f. Mineralogie*, 1872, 98); *Chem. Soc. J.* [2], x, 796).

On the character of the crust produced upon terrestrial rocks by atmospheric agency, compared with the black coating of certain meteorites, see S. Meunier (*Compt. rend.* lxxv. 890; *Chem. Soc. J.* [2], xi. 141).

ROMBIN. From a recalculation of Damour's analysis of this mineral (v. 116) Kenngott (*Jahresb. f. Mineralogie*, 1870, 999) deduces the formula:

ROOT-CROPS. The principal root-crops cultivated by the farmer are:—Turnips, *Brassica Rapa* (Fr. *navet*, Ger. *Turnipsrübe*, *Weissrübe*); Swedes, *B. campestris*; Beet, *Beta vulgaris*, of which two main varieties, Mangel-wurzel (Fr. *betterave*, Ger. *Futterrunkelrübe*), and Sugar-beet (Fr. *betterave-à-sucré*, Ger. *Zuckerrübe*) are cultivated; Carrots, *Daucus Carota* (Fr. *carotte*, Ger. *Möhre*); and Parsnips, *Pastinaca sativa* (Fr. *panais*, Ger. *Pastinakwurzel*). These plants are all biennials, the first season being devoted to storing up matter in the root, and the second season to the production, out of the matter so accumulated, of a flowering stalk, and seed. As the root is in every case the part which is of economic importance, the attention of chemists has been concentrated upon the first period of the plant's life, and the second stage of growth has been little studied.

The composition of a cultivated root will depend—1. On its species; 2. On its size; 3. On its maturity, dependent upon its age and the climate it has been exposed to; 4. On the character of the soil and the manure employed. The differences of composition between various kinds of roots are shown in the table on p. 1049, which, except in the case of sugar-beet, gives the mean of all available analyses. The amount of variation among these analyses which yield the above means is, in most cases, very considerable; one cause is the distinctive characters of the different varieties of the same root; other circumstances which produce variations in composition will be considered presently.

The specific gravity of roots is generally less than that of their sap. Turnip root in water, Swedes of good quality sink. The sp. gr. of Swede sap is 1.016–1.024 (Murray). Sugar-beet sap rises sometimes to 1.08. The sp. gr. of sugar-beet roots rises and falls with that of the sap in the case of small roots, but with large roots discrepancies occur from the presence of air spaces.

The dry matter in fresh roots varies from 6–7 p.c. in some white turnips, to 21 p.c. in high quality sugar-beet. Roots begin to lose water as soon as they are pulled from the field; determinations of water are therefore frequently too low.

Average percentage Composition of Roots.

	Number of Analyses *	Water	Albuminoids	Fat	Extractive matter	Sugar	Cellulose	Ash
Turnips . . .	23	91.79	1.17	.20	1.85	3.22	1.08	.69
Swedes . . .	31	89.32	1.47	.20	2.06	5.25	1.10	.60
Mangels . . .	61	88.68	1.22	.10	1.45	6.23	1.32	1.10
Sugar-beet . . .	78	83.62	1.47	.10	2.43	10.10	1.42	.86
Carrots . . .	24	85.81	.97	.25	2.79	7.33	1.81	1.04
Parsnips . . .	2	85.17	1.44	.37	8.05	2.91	1.25?	.81

Average percentage Composition of Leaves.

Turnips . . .	27	86.60	2.71	—	8.93	—	—	1.76
Swedes . . .	26	85.00	3.78	—	9.47	—	—	1.75
Mangels . . .	15	90.93	1.74	.50	3.76	1.16	—	1.91
Sugar-beet . . .	12	88.80	2.32	—	4.16	1.90	—	2.82
Carrots . . .	2	79.35	3.51	1.14	9.33	3.22	—	3.45
Parsnips . . .	1	83.15	1.81	.40	9.88	2.17	—	2.50

The nitrogen in roots is by no means all in the form of albuminoids, though calculated as such in analyses; the figures given for albuminoids are therefore in every case too high. E. Schulze (*Landw. Versuchs-Stationen*, ix. 445; xv. 170) found in mangels 0.37–3.13 of nitric acid in 100 of dry substance; the mean of 21 specimens was 1.44 p.c. In the extreme case 31 p.c. of the nitrogen in the root existed as nitrates. Six kinds of turnips gave a mean of 0.276, and three specimens of carrots 0.189 p.c. of nitric acid in their dry substance. Frühling found, in the dry matter of the leaves of sugar-beet, 0.28–1.60 p.c. of nitric acid. Schulze has determined the ammonia in the sap of various roots; in mangels it varied from 0.0084–0.0223 p.c. of the fresh sap; the mean of eight examples was 0.0158 p.c.; in the sap of four carrots the mean was 0.0215 p.c. Ammonia is found in the condensed water from evaporating the juice of sugar-beet. According to Hesse, trimethylamine and ammonia are present in the sap of the leaves. Asparagine has been found by Scheibler in sugar-beet, and is probably generally present in roots in small quantity; in sugar-beet which had been stored Scheibler found aspartic acid. Betaine, the nitrogenous base discovered by Scheibler in the sap of sugar-beet, has been already described (see *BETAINES*, 1st Suppl. 340; 2nd Suppl. 186); the percentage of betaine in the sap diminishes as the root matures. Scheibler found .234 p.c. in the sap on July 1, and .084 p.c. on October 1. In the molasses of the sugar-beet factories the betaine reaches 1.59–2.78 p.c. The nature of the albuminoids in roots has not been thoroughly investigated; they appear to contain both legumin and albumin. In sugar-beet the cambium is said to be the part of the root richest in albuminoids. In parsnips Voelckor found that the intermediate layer separating the heart from the exterior was by much the most nitrogenous.

The fatty matter of roots has not been especially investigated; according to König the fat in beet-root is chiefly concentrated in the rind. The fat mentioned in the analyses as present in the leaves doubtless includes chlorophyll.

Sugar is one of the most important constituents of cultivated roots, and upon it their feeding value greatly depends. In the case of sugar-beet, by careful selection of seed and appropriate cultivation, the proportion of sugar has been raised to 13–14 p.c. for small roots, and under exceptional circumstances much higher quantities are obtained; according to Vilmorin 21 p.c. has actually been reached in some cases. Sugar is not uniformly distributed in beet-root; the cellular tissue which lies in contact with the cambium is the richest. The top of the root is always poor in sugar; the proportion, according to Viollette, increases regularly downwards. Sebor, however, found the extremity poorer than the centre. The sugar in beet-root is almost entirely saccharose, only a very small quantity of glucose and levulose being present; this quantity increases, however, when the roots are stored, especially, according to Pasteur, if

* These numbers refer to analyses in which water, nitrogen, and ash have all been determined; determinations of fat, cellulose, and sugar are in most cases much lower. Where isolated determinations have been introduced, they have been recalculated so as to accord with the mean dry matter. Thus the sugar in Swedes is the mean of 4 determinations by Sullivan. He found 7.26 p.c.; but the dry matter in his roots, which had been exposed some weeks, was 14.75 p.c.; the sugar therefore in 100 of dry matter is 6.26.

the heap of roots is ill-ventilated, and carbonic acid is allowed to accumulate. The sugar in the leaf and leaf-stalk of sugar-beet is, according to Méhay (*Jahresb. Agri. Chem.* 1868-9, 278), almost entirely uncrystallisable. In carrots a large proportion of the sugar is, according to Dietrich, in the form of glucose (fructose, Brotschneider); mannite has also been found in this root.

Starch has not been recognised in turnips or Swedes; in unripe sugar-beet a small quantity has occasionally been found by Sullivan, which disappeared as the root matured. In wild carrots starch is abundant; in cultivated carrots the quantity is much diminished, and may apparently disappear altogether, being probably replaced by sugar. Karsten found 6·8 p.c. of starch in carrots; Voelcker found none. Parsnips also contain starch; Voelcker found 3·5 p.c. in the fresh root. In both carrots and parsnips the starch is deposited next the rind; the internal parts of the parsnip, according to Voelcker, contain no starch.

The insoluble fibrous matter of roots, which forms the substance of the mark when roots are pressed, consists of cellulose, a small quantity of lignose (suberin), which constitutes the cuticle of the root, and a more or less considerable amount of pectose. Scheibler (*Deut. Chem. Ges. Ber.* vi. 612) has also shown that in the sugar-beet of some seasons a considerable amount of insoluble arabin (metarabin) is present. The arabin appears to consist of two bodies—the principal, a powerfully levorotatory substance, yielding arabinose, a right-handed crystalline sugar, when acted on by dilute sulphuric acid; the other, a closely allied body, apparently dextrorotatory, which, on treatment with sulphuric acid, yields a non-crystalline sugar. These bodies have not yet been separated. Only a few determinations of cellulose have been made in roots, the crude fibre being generally weighed without previous separation of the pectose; both pectose and metarabin may be removed by boiling the crude fibre with an alkali.

H. Schultze a. E. Schulze (*Landw. Versuchs-Stationen*, ix. 439) have made ultimate analyses of the mark of roots from which all matter soluble in cold water had been removed; in the case of carrots the mark was previously treated with malt-extract to remove the starch.

	Composition of Mark					Mark after deducting albuminoids and ash		
	C	H	O	N	Ash	C	H	O
Mangel, unripe	44·80	6·11	45·07	1·21	2·81	45·50	6·22	48·28
Mangel, after wintering	44·92	5·92	46·21	·73	2·22	45·69	6·01	48·40
Carrot, after wintering	43·34	5·78	46·53	1·19	3·16	44·07	5·80	50·04

The numbers for the pure carbo-hydrate differ little from the composition of cellulose; the differences in the first two analyses are in the direction of lignose, and in the last in the direction of pectin. It is evident in the case of mangels that the insoluble albuminoids and ash found in the mark diminish as the root matures.

The mark obtained from beet-root in the sugar-factories on the continent is largely consumed as a cattle-food; the average composition of the residua obtained by the old process of pressure, and by the newer and more effective plan of diffusion, is about as follows:

	Water	Albuminoids	Fat	Sugar	Extractive matter	Cellulose	Ash
Press residue	70·00	1·84	0·20	3·00	16·83	5·13	3·00
Diffusion residue	91·62	0·67	0·07	6·30	4·75	1·75	0·64

The diffusion residue contains in the dry more albuminoid than the press residue; the large amount of ash is owing to the earth adhering to the roots.

Of the organic acids present in roots, oxalic acid is the most important; it is present in mangel and sugar-beet, and reaches a high percentage in their leaves. The sap of sugar-beet, according to Michaelis, contains '08 p.c. of oxalic acid, and '11 p.c.

of citric acid; this oxalic acid is, of course, in a soluble form. The total oxalic acid in the root of sugar-beet was found by Méhay to be 22 p.c.; the leaf-stalk of the same roots contained 43 p.c., and the leaves 1.86 p.c. A. Müller puts the oxalic acid in mangel leaves at 2 p.c., with citric and malic acid 15 p.c. Mittenzwey has shown (*Landw. Versuchs-Stationen*, i. 242) that the different circles of mangel leaves contain very different amounts of oxalic acid; the innermost youngest leaves gave 1.85 p.c. of oxalic acid in their dry matter; the outermost oldest leaves 10.98 p.c.; the percentage rose regularly from the innermost to the outermost leaves. About two-thirds of the acid existed pretty uniformly in an insoluble state. Cattle are occasionally poisoned by eating the leaves of mangel. Oxalic and tartaric acids have been mentioned as present in turnip leaves; carrots are said to contain malic acid.

The colouring matters of roots do not appear to have been investigated, save in the case of carrots (see CAROTIN, i. 805).

Ultimate analyses of the whole substance of turnips and mangels have been made by Boussingault, and by Richardson (*Jour. Roy. Agri. Soc.* xiii. 458), and ultimate analyses of mangels and carrots by H. Schultze (*Landw. Versuchs-Stationen*, ix. 439).

The average composition of the ash, both of roots and leaves, is shown in the following table; the figures are the mean of nearly all the available analyses. The percentage composition has been calculated after deduction of carbonic acid, but the amount of carbonic acid in the original ash is also given as far as it could be ascertained; in the German analyses it is usually omitted.

Average Composition of the Ash of Roots, Carbonic Acid deducted.

	Number of analyses	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ²	Cl	SiO ²	CO ² in original ash
Turnips . . .	38	49.8	7.8	11.7	2.6	.9	10.3	11.8	5.0	1.2	14.0
Swedes . . .	7	38.9	14.0	12.8	4.2	.8	10.4	13.7	4.2	1.9	12.9

Mangels . . .	4	25.5	23.3	10.4	9.7	1.2	6.4	7.2	17.8	3.3	14.5
Sugar-beet . .	7	21.9	16.6	19.5	18.1	1.3	7.3	7.9	5.7	3.1	—
Carrots . . .	7	17.6	18.2	32.1	3.9	3.0	3.8	8.2	8.9	5.2	10.1

The range of variation in these analyses is, in every case, very great. The most constant ingredients in the ash of roots are those most essential to plant-life, potash and phosphoric acid; the most variable constituents are soda and chlorine. The variations in the ash-constituents of the leaves are even greater than in the case of roots.

The ashes of all the roots are, on the whole, of similar character. The ashes of the Brassicæ are particularly rich in sulphates, both in root and leaf. The ash of mangel and of sugar-beet differ from each other considerably in some points, though the plants are the same species. In cultivating sugar-beet the aim is to obtain roots with a small amount of ash, as saline matter prevents the crystallisation of the sugar, and to this end small roots, scantily manured, are produced; mangel is, on the other hand, cultivated with a view to bulk. The small ash of the sugar-beet is of a concentrated nature, rich in potash, phosphoric acid and magnesia. The large ash of the mangel are apparent, but in this case the large amount of lime in sugar-beet is probably due to the greater maturity of the plant when harvested. Peligot remarks that beet is one of the plants in which soda is always found abundantly, while parsnips are destitute of soda; and this difference is maintained even when beet-root and parsnips are cultivated in the same bed. Rubidium occurs in minute quantity in the beet-root of the north of France, and may be obtained from the ash of the residue which remains after distill-

ing the fermented molasses. According to Lefebvre, the amount of rubidium chloride in an average crop of sugar-beet is 224 grams per hectare; Pfeiffer estimates the quantity at 255 grams. A trace of cesium, and small quantities of iodine and bromine, but no lithium, were found by Pfeiffer in the same ash. Manganese has also been recognised in the ash of sugar-beet.

The ash of the leaves is seen to have a very different composition from that of the roots, the potash and phosphoric acid being much smaller, and the lime and chlorine far greater. In connection with the large amount of chlorides in the leaves, Peligot and Viollette have observed that the chlorides in the root of sugar-beet are most abundant at the neck, and decrease from this point downwards.

The amount of carbonic acid in all these ashes should correspond with the combined amounts of organic salts and nitrates present; the various temperatures, however, at which the ashes have been burnt, prevent any stress being laid on the figures given in the table.

Having described the general composition of the various plants grown as root-crops, we turn to the circumstances which modify this composition. Luxuriantly growing plants always contain more water, and, as a rule, more nitrogen and ash, than less vigorous plants of the same age; this is true of roots, and consequently large roots and small ones, taken at the same time from the same field, exhibit considerable differences in composition. The following comparative analyses by different chemists will illustrate this point.

	Water	Nitrogenous matter	Sugar	Extractive matter	Crude fibre	Ash
Mangel, 9 lbs. .	91.85	1.34	2.86 3.95	2.54 4.51	1.41 0.82	
„ 7½ lbs. .	89.48	1.24				
Mangel, 4 lbs. .	89.77	0.73	7.68 10.51	0.89 1.07	0.93 0.91	
„ 1-2 lbs. .	86.90	0.61				
Sugar-beet, 5½ lbs. .	88.01	2.08	5.60	1.93	2.38	1.10
„ 1½ lbs. .	84.35	1.17	8.10	5.28		

It is evident from these facts that small roots will always contain a larger proportion of nutritive matter than large roots of the same age. The feeding power of a crop is thus not necessarily in proportion to its weight; the more bulky the crop the smaller is the proportion of solid matter it contains. The differences of composition due to the size of the root are more strikingly seen in the case of beet than with other root crops. Small mangolds approach sugar-beet in composition; over-grown sugar-beets are quite similar to mangels. To obtain sugar-beet of the highest quality it is well known that the roots must not exceed 2 lbs. in weight.

One reason of the difference between large roots and small ones of the same age is that the more bulky root is less mature than the small one; this brings us to the next point, the effect of age on the composition of root-crops. The composition of the turnip plant in different stages of growth has been investigated by Anderson (*Trans. Highland Soc.* 1860, 307, 360), and by Wunder (*Jahresb. Agri. Chem.* 1861-2, 74, 107). Mangel-wurzel has been investigated by Wolff (*ibid.* 1860-1, 139), and its leaves by A. Müller and Mittenswey (*Landw. Versuchs-Stationen*, i. 241). Sugar-beet has been studied during its first stage of growth by Bretschneider (*Jahresb. Agri. Chem.* 1860-1, 129; 1861-2, 88, 261), Hoffmann (*ibid.* 1862-3, 119), Eylarts (*ibid.* 128), Nobbe a. Siegert (*ibid.* 69), Scheibler (*ibid.* 1870-2, iii. 286), Lotmann (*ibid.* 287), and Church (*Trans. High. Agri. Soc.* [4], iv. 85). The changes in its sap have been observed by Hoffmann (*Jahresb. Agri. Chem.* 1860-1, 132; 1861-2, 83), and Méhay (*ibid.* 1870-2, iii. 285). The second period of growth, in which seed is produced, has been studied by Hoffmann (*ibid.* 1861-2, 87), and by Corenwinder (*ibid.* 1867, 126). Carrots have been investigated by Bretschneider (*ibid.* 1861-2, 101).

In the life of all root-crops the leaf is the part which is at first most actively developed, but as growth proceeds the proportion of root to leaf steadily increases. When active growth comes to an end the older leaves wither and fall off, a considerable part of their constituents being transferred to the root. Anderson's research on turnips will serve to illustrate the general relation of leaf to root, and at the same time supply information on the turnip crop. The crop amounted to 16 tons of roots per acre; it was heavily manured.

Composition of a Turnip Crop at various periods in lbs. per acre.

	July 7		August 11		September 1		October 5	
	Leaf	Root	Leaf	Root	Leaf	Root	Leaf	Root
Organic matter . . .	16.13	1.16	990	190	1720	1293	1084	2762

Silica	0.01	0.02	7.2	.6	10.3	4.5	7.5	22.8

On July 7 the dry matter of the root was to that of the leaf as 8 : 100; on October 5 the proportion was 270 : 100.

The results of Wunder and of Anderson in their three series of experiments with turnips are somewhat discordant; we will therefore mention only some general facts.

As a rule the composition of a root-crop undergoes the following changes. In the seedling the proportion of dry matter is at its maximum; the water, in both root and leaf, afterwards increases up to the period of most active growth, but as the plant matures the water again diminishes. In the case of turnips the increase of dry matter in the root during the latter part of its growth is but little marked, and is apparently confined to the latest stage. The nitrogen in the dry matter is also at its maximum in the seedling (Anderson and Wunder both found 5-6 p.c. of nitrogen in seedling turnips), and falls afterwards both in root and leaf. With turnip-roots the nitrogen appears to rise after the first fall until the last stage is reached, when the amount again diminishes. The amount of ash in the dry matter of the root tends to diminish as the plant matures. With turnip-root the ash, after falling, rose in all cases during the final stage of growth. The proportion of ash in the dry matter of the leaves is often more constant than in the root; in the case of turnip-leaf the ash appears to diminish as the plant matures; probably, however, rising again when withering commences. The maximum content in nitrogen generally occurs very early in a plant's life, the maximum contents in water and ash generally coincide with the period of most active growth.

The relative proportion of the ash-constituents, as shown in the composition of the ash per cent., varies during the growth of the turnip as follows. In leaf and root there is in the first case a rise in potash, which, in the case of the root, is very considerable, and a corresponding fall in lime and magnesia. The potash in the leaf generally diminishes somewhat in the last stage of growth, the other bases rising. Chlorides increase steadily in the leaf throughout its growth. At the end of the growing time the root-ash is richer both in potash and phosphoric acid than at the beginning, and poorer in lime and magnesia; the last-named bases rise somewhat in the final stage of growth. The changes in the leaf-ash are more irregular.

In Bretschneider's experiments with carrots the alterations in composition were very regular. His experiments did not commence with the seedling; the great changes which usually occur in the primary stage were therefore not observed. In the leaf the dry matter was at its minimum (11.61 p.c.) on August 14, and then rose steadily to 17.72 p.c. on October 10. The dry matter of the root slowly increased from the first, and, with but one irregularity, reached its maximum at the end of the experiment. The amounts of nitrogen and ash in the dry matter of the root regularly diminished. The dry matter in the root was to that in the leaf as 34 : 100 on July 25, and rose to 87 : 100 at the close of the experiment. Bretschneider's analyses of the carrot-root in various stages are very typical of the changes which usually take place in root-crops; his results were as follows:

	Carrot-root, fresh					Carrot-root, dry				
	July 25	Aug. 14	Sept. 4	Sept. 19	Oct. 10	July 25	Aug. 14	Sept. 4	Sept. 19	Oct. 10
Water . . .	90.58	90.20	89.95	90.47	89.24	—	—	—	—	—
Albuminoids . .	1.10	1.00	1.03	.83	.73	11.67	10.20	10.24	8.71	6.78
Extractive matter .	2.34	2.11	1.89	1.95	2.10	24.84	21.53	18.80	20.46	19.51
Cane-sugar . .	1.17	1.04	1.30	1.35	2.49	12.42	10.61	12.94	14.17	23.14
Fruit-sugar . .	8.18	3.65	3.91	3.63	3.59	33.23	37.25	38.91	38.09	33.37
Fibre . . .	1.07	1.31	1.29	1.20	1.20	11.36	13.37	12.84	12.59	11.16
Ash . . .	0.61	0.69	0.63	0.57	0.65	6.48	7.04	6.27	5.98	6.04

The total sugar in the dry matter steadily increases, but at first it is the fruit-sugar which rises, and afterwards the cane-sugar. The fibre comes to a maximum early in the growth, and then diminishes.

The ash-analyses of the carrot-root and leaf exhibited little variation during the experiment; the percentage composition of the ash (carbonic acid deducted) was in the first and last stages as follows:—

	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	Cl	SiO ²
Leaf, July 25 . .	18.12	30.80	20.89	7.67	1.23	7.30	7.26	5.07	2.80
„ Oct. 10 . .	14.68	28.70	27.45	6.70	1.86	6.38	9.72	2.71	2.40
Root, July 25 . .	28.67	34.67	8.75	5.72	0.39	13.19	4.44	2.55	2.19
„ Oct. 10 . .	30.48	28.88	11.53	6.46	0.40	14.99	3.49	2.08	2.08

In the case of sugar-beet, the alteration in the composition of the root during growth is far more striking than in the preceding instances; the following are Bretschneider's results. His experiment, as in the case of carrots, did not commence at the youngest stage. The proportion of the dry matter in the root to that in the leaf was at the commencement, on July 20, 61 : 100; it had risen by October 16 to 417 : 100.

	Sugar-beet roots, fresh						Sugar-beet roots, dry					
	July 20	Aug. 9	Aug. 31	Sept. 15	Sept. 30	Oct. 16	July 20	Aug. 9	Aug. 31	Sept. 15	Sept. 30	Oct. 16
Water . . .	88.78	88.99	86.62	85.46	82.19	82.19	—	—	—	—	—	—
Albuminoids . .	2.08	2.35	2.01	2.13	2.48	2.28	18.61	18.67	15.06	14.74	13.92	12.84
Extractive matter } .	2.61	1.67	1.66	1.30	1.53	1.85	23.12	17.86	11.61	8.92	8.01	10.10

Fibre . . .	1.17	1.09	1.01	1.21	1.22	1.10	10.50	9.89	8.30	8.34	7.43	6.42
Ash . . .	0.82	0.75	0.89	0.73	0.77	0.68	7.31	6.81	6.66	5.02	4.33	3.83

We see that after August 9 the beet-root increased rapidly in dry matter, and that this increase was practically an increase of sugar, the composition of the dry substance showing a regular fall in nitrogen, ash, fibre, and extractive matter, and a corresponding rise in cane-sugar. The sap, forming as it does the mass of the root, undergoes a similar change. Sugar-beet, when harvested, contains about 4 p.c. of insoluble matter; the rest is sap. The proportion of ash and nitrogen in the sap falls considerably in the earliest stages of growth, and then remains tolerably constant; the sugar, however, continues to increase; the relation, therefore, of the soluble impurities (*Nichtzucker*) to the sugar steadily diminishes. Thus in Scheibler's experiments the sap contained, on July 1, 66.01 of soluble impurity for 100 of sugar; but on October 1 the proportion

had become 12.89 : 100, and the percentage of sugar in the dry matter of the sap (*Zuckerquotient*) had increased from 64.1 to 88.6. This is, of course, the view of the question specially regarded by the sugar manufacturer.

In Bretschneider's investigation the alteration in the composition of the leaf was as follows:

	Sugar-beet leaf, fresh						Sugar-beet leaf, dry					
	July 20	Aug. 9	Aug. 31	Sept. 15	Sept. 30	Oct. 16	July 20	Aug. 9	Aug. 31	Sept. 15	Sept. 30	Oct. 16
Water . . .	88.78	90.50	90.28	87.33	86.92	79.31	—	—	—	—	—	—
Albuminoids	3.16	2.81	2.03	2.58	2.60	3.95	28.04	29.56	20.89	20.38	19.88	19.12
Extractive matter	4.42	3.54	4.48	5.88	6.35	8.92	39.46	37.32	46.10	46.39	48.56	43.09
Fibre . . .	1.46	1.51	1.40	1.95	2.06	3.98	13.00	15.86	15.32	16.39	15.73	19.24
Ash . . .	2.19	1.64	1.72	2.26	2.07	3.84	19.50	17.26	17.69	17.84	15.83	18.55

August 9 is, as in the case of the root, the date from which the increase in dry matter commences. The proportion of nitrogen in the dry matter is seen to diminish rapidly at first, and afterwards to be but slightly altered. The ash after falling rises again at the last. A rise in the incombustible matter of leaves always takes place when withering has commenced. A Müller found 30 p.c. of ash in the dry matter of yellow mangel-leaves collected in August, while green leaves collected on the same day gave 17 p.c. The withered leaves contained also less water. The extractive matter in the analyses includes sugar; it therefore rises, instead of falling, as in the root.

The changes which take place in the leaves of a root-crop are much complicated by the fact that new and old leaves are very dissimilar in composition. Bretschneider examined separately the different circles of leaves formed by sugar-beet. The youngest, innermost leaves contained 10.88 p.c. of dry matter, and this dry matter contained 8.35 p.c. of ash. The amount both of water and ash steadily increased from the centre outwards, till the 6th, outermost circle of leaves, which contained 8.91 p.c. of dry matter, and 15.98 p.c. of ash in the dry. Mittenzwey found a yet wider variation among mangel leaves, the innermost giving 12.01 p.c. of dry substance, and 14.3 p.c. of ash in dry, and the 7th outermost circle 8.64 p.c. of dry matter, and 31.16 p.c. ash in dry. His interesting results as to the increase of oxalic acid from the youngest leaves to the oldest have been already mentioned.

Bretschneider made complete analyses of the ash of the root and leaf of sugar-beet at each of the periods mentioned above, and also on another occasion analysed the ash of the different circles of sugar-beet leaves. The following selection will give some idea of his results:

	K ² O	Na ² O	CaO	MgO	Fe ² O ³	P ² O ⁵	SO ³	Cl	SiO ²
Root, July 20 . . .	48.00	14.25	3.44	7.89	.73	15.99	4.22	2.76	3.34
" Oct. 16 . . .	44.08	5.78	6.46	10.48	1.15	17.85	8.89	2.97	3.06
Leaf, July 20 . . .	17.75	18.19	12.04	25.93	1.65	10.38	4.89	9.73	1.65
" Oct. 16 . . .	22.62	12.86	18.20	16.46	1.21	9.17	8.34	7.20	5.58
Leaf, innermost . .	50.27	14.57	4.76	6.71	0.51	12.69	5.86	3.97	1.56
" outermost . . .	18.74	18.26	24.20	24.48	1.42	3.30	5.37	3.50	1.52

The alterations brought about by age are on the whole similar to those observed in the case of carrots (see above); the large increase of lime in both leaf and root is in all cases a marked feature. Bretschneider remarks that the sugar contents of the root is greater the smaller is the proportion of the alkalis to the alkaline earths; the diminution of this proportion is, in fact, an indication of an advancing maturity. The same rise in lime was also observed in some of the investigations on turnips. The difference between the ash of the youngest and oldest leaf, existing together on the same plant, is seen to be far greater than that between the total leaves gathered at remote periods.

The different circles of leaves in beet-root are in connection with corresponding

cylindrical layers of the root. The plant grows by producing first fresh leaves, which form a new innermost circle, and from these leaves a new exterior layer of the root takes its rise. The function of new leaves is thus to increase the size of the root; the function of the mature leaves is to store up matter in the root layers already formed. In experiments by Schacht it appeared that removing full-grown leaves did not necessarily lessen the weight of the root at harvest, but it considerably diminished the proportion of sugar. The composition of the ash of the youngest leaves is seen to be of the most concentrated character, rich in potash and phosphoric acid, and corresponds with their function of producing new tissue. Bretschneider separated the various layers of beet-root and examined them separately; his results have unfortunately not been published in the *Jahresbericht*.

The changes in mangel-wurzel during growth should be similar to those in sugar-beet; the crop, however, being always highly manured, the period of active growth is long continued, and the increase of dry matter and sugar which should take place during ripening occurs to only a small extent.

When roots are taken from the field and stored for future consumption, they slowly lose in weight, carbonic acid and water being evolved. The quality of the root for feeding purposes is, in the case of mangel, much improved by wintering, but the precise nature of the change has not yet been investigated.

The changes which occur during the second year of the life of a root crop have been investigated only in the case of sugar-beet. The fresh development of leaves in the spring is accompanied by a considerable diminution of sugar, but after this point the amount of sugar remains unchanged until the formation of seed commences. When the seed is ripe, the root is found to be destitute of sugar, and also to have lost the whole of its phosphoric acid. A large increase of nitrates in the root takes place during the formation of seed; the nitrates disappear as the seed ripens. A root which had produced ripe seed contained, according to Corenwinder, water 90.35, cellulose 2.95, pectose and extractive matter 4.58, ash 2.12 p.c. When, however, as sometimes happens, a sugar-beet runs to seed in the first year of its life, the alterations are much less marked. The production of seed being less vigorous, the root retains a considerable amount of sugar (½ths, according to Church); it contains, however, more cellulose, ash, and less phosphoric acid.

The seeds of root-crops have been little examined. For ash-analyses of mangel, turnip, and carrot seed, see vol. i., pp. 583, 655, 807.

We have now to consider the last condition affecting the composition of root-crops—the influence of soil and manure. The effect of the composition of the soil, both on the bulk and composition of root-crops, is best illustrated by the results obtained at Rothamsted. Mr. Lawes' experimental field has grown roots since 1843, and similar manures having been applied every year to the same plots, the conditions of the soil have become very distinct. The following selection of unpublished results relating to turnips, swedes, and sugar-beet has been kindly communicated by Messrs. Lawes and Gilbert.

We must first look at the proportion of leaf to root at the time of harvest. Other things being equal, a low proportion of leaf to root signifies, as we have already seen, maturity in the root, while a high proportion shows that the crop is still in a growing condition. Looking at the character of the white turnips manured by superphosphate alone, and with various nitrogenous manures in addition, we see that each increase in the amount of nitrogen is followed by a large increase in the proportion of leaf, and consequently by a less matured produce. The composition of the turnips varies in the same direction. In the less mature crops the percentage of dry matter falls in both root and leaf, and the percentage of ash and nitrogen in the dry matter of the root rises. The effect of the manures is here perfectly consistent with the facts previously mentioned. The addition of nitrogen to phosphatic manure produces larger roots and a prolonged period of active growth, and is attended with the same alteration in composition of the crop as we have already seen accompany increase of size and deficient maturity. In the case of Swedes the changes produced by the addition of nitrogen to superphosphate are in the same direction as with turnips, but the alterations in the proportion of leaf, and in the ash, are less conspicuous. With sugar-beet the changes in composition, with a similar series of manures, are very well marked; the percentage of sugar clearly follows the other signs of maturity.

Besides these general facts, the tables show us that where alkalis (in these experiments, sulphates of potassium, sodium, and magnesium) are employed, the amount of leaf is always much less, and the proportion of ash in the produce greater. The effect of alkalis on the leaf explains the anomalous proportion of leaf in the sugar-beet manured with sodium nitrate in the first series. In the second series in the table all the plots receive alkalis, and in this case the lesser maturity of the beet grown with sodium nitrate is correctly shown by the larger proportion of leaf.

The unmanured turnips have a distinct character from those hitherto considered: with a large proportion of leaf, they have also a very high dry matter, and a comparatively low ash. In this case the crop is so small that no active growth can have taken place; the root thus remains with a low percentage of water, though still immature. For the same reason these diminutive roots are very rich in nitrogen. We have already remarked that the turnip seedling contains 5-6 p.c. of nitrogen in its dry matter, and that this high percentage diminishes as soon as active growth sets in. In 1846 the nitrogen was determined in the unmanured white turnips, which that year weighed less than 2 ozs. a piece; it amounted to 3.31 p.c. of the dry matter, a greater proportion than was yielded by any of the manured turnips.

The tables show that the composition of the leaf is less affected by manuring than the root. The percentage of nitrogen in the leaf remains very constant, and the variations in the ash are on the whole less.

We see from these experiments, that when turnips are grown with superphosphate only, the crop comes early to maturity; and that when nitrogenous manures are added to the superphosphate, the crop at the end of the autumn is less mature, and contains a smaller amount of dry matter, and more ash and nitrogen. For the reason, however, that growth is not concluded, the latter crop is better able to withstand the effect of frost.

The feeding value of turnips is by no means in proportion to their contents in nitrogen. In 1848 Mr. Lawes determined, by experiments with sheep, the feeding value of four lots of white turnips from the experimental field; the percentage composition of the turnip and the result of the trial were as follow:—

	Nature of manuring			
	Cinereals only	Cinereals with ammonia	Cinereals with rape-cake	Cinereals, ammonia, and rape-cake
Dry matter in fresh	9.37	8.42	7.78	7.88
Ash in dry	6.69	7.48	8.21	8.92
Nitrogen in dry	1.56	2.08	2.36	3.20
Dry organic matter consumed to produce 100 lbs. of live weight)	lbs. 2288	lbs. 1321	lbs. 2371	The sheep lost weight

The turnips grown by superphosphate and alkalis only were over-ripe and pithy; the second lot, which gave the best result, were fully ripe; the third and fourth lots were not ripe. The most unripe and nitrogenous turnip gave, it is seen, the worst result when employed as food. For further information as to the effect of manures on the turnip-crop, see Mr. Lawes' paper (*Jour. Roy. Agri. Soc.* viii. 495).

Numerous experiments have been made upon the influence of manures on the percentage of sugar in beet-root. The manures which have the most favourable effect appear to be superphosphate and potash salts; as, however, such manuring yields a very small crop, a limited quantity of nitrogenous manure must also be applied. Any large application of nitrogenous manure so as to produce bulky roots will, except under exceptional conditions, greatly lower the proportion of sugar in the roots. In field experiments it is not unusual to find that the unmanured plot yields the roots richest in sugar.

The influence of the constituents of the soil on the composition of the ash of roots is considerable, as proved by the variations exhibited in different ash-analyses. Potash and soda are clearly replaceable to some extent. In the ash-analyses of which the mean has been already given (p. 1061), the variations were—in mangel-root: potash 69.2-25.2, soda 38.9-5.2; in sugar-beet: potash 58.9-22.0, soda 29.8-6.1; in carrots: potash 50.9-17.0, soda 34.8-10.1. From numerous experiments made on the continent, it appears that the supply of potash and phosphoric acid to sugar-beet is attended with a distinct rise of these substances in the ash. Manuring with chlorides has, however, the most marked effect. The percentage of chlorine may be readily doubled or tripled if a considerable amount of chlorides be applied in the manure. Common salt is frequently employed as a manure for mangels, and the amount of chlorides sometimes amounts to half the weight of the ash (49.5 p.c. Way). The analyses by Gilbert & Campbell of the ashes of the experimental turnips at Rothamsted point to the same general conclusions.

Assuming that average root-crops will be: turnips, 17 tons roots, root, & leaf

100 : 30; Swedes, 14 tons roots, root to leaf 100 : 15; mangels, 22 tons roots, root to leaf 100 : 37; sugar-beet, 10 tons roots, root to leaf 100 : 25; carrots, 10 tons roots, root to leaf 100 : 40*; the quantities of the principal constituents removed in the crop will be in lbs. per acre about as follows. The total ash is reckoned without carbonic acid :—

	Nitro- gen	K ² O	Na ² O	CuO	MgO	P ² O ⁵	SO ²	Cl	SiO ²	Total ash

The quantity of plant-food removed from the soil by root-crops is very large. An average crop of wheat, barley, or oats, will not contain more than 50 lbs. of nitrogen in corn and straw, nor more than 100 lbs. of ash-constituents, of which only about 30 lbs. will be potash and 19 lbs. phosphoric acid. Root-crops, if removed from the land, are therefore far more exhausting than corn-crops, and especially in respect of alkalis.

It was formerly imagined that the turnip, by means of its widespread foliage, was able to procure a large amount of nitrogen from the atmosphere, and that in this lay the secret of its usefulness in a rotation. The Rothamsted experiments have shown, on the contrary, that turnips are greatly dependent on the nitrogen of the soil, and, when they are grown for successive years with purely cinereal manures, impoverish the soil of nitrogen to a far greater extent than would result from a similar cropping of wheat or barley. It is probable, indeed, that a part of the advantage of turnip culture arises from the crop utilising soil-nitrogen existing in conditions unsuitable for cereal crops. Notwithstanding the greater capacity of root-crops for appropriating soil-nitrogen, nitrogenous manures must generally be employed if maximum crops are desired. Nitrates appear, from the experiments at Rothamsted, to have a distinctly greater effect both on Swedes and beet, than the same amount of nitrogen applied as ammoniac.

Turnips are apparently well able to supply themselves with alkalis from the soil, applications of potassium salts scarcely increasing the produce, except on poor light soils. The crop is, on the other hand, clearly deficient in the power of appropriating soil phosphates, applications of soluble phosphates producing a great effect on the crop. Turnips also appear more dependent on the soil for a supply of carbonic acid than is the case with cereal crops, organic manures, such as farmyard-manure and rape-cake, producing a relatively greater effect than with wheat or barley.

Analysis of Roots.—All adhering soil is first removed by washing, and the root wiped dry. Leaves and stalks are then cut off, and, in the case of sugar-beet analysed for manufacturing purposes, the green upper part of the root is also removed, as this is always separated by the sugar manufacturer. The root is then divided into quarters, or other convenient portions, by cutting it exactly through the middle from top to

* The data for this proportion are very meagre.

bottom; thus prepared, each segment will fairly represent the whole, if the root is symmetrical. Water is determined in a segment of about 100 grms.; the weighed portion is cut into thin slices, strung on a wire, dried first at a very low temperature, and finally at 110° . Saccharine substances being difficult to desiccate, the drying is best completed in a current of dried air. The dry matter is very hygroscopic. Total nitrogen, ash, and fatty matter are determined in the powdered dry matter by the ordinary methods. To determine nitrogen present as nitrates, H. Schultze and E. Schulze (*Landw. Versuchs-Stationen*, ix. 445) extract 5–10 grms. of the powdered dry matter with hot 90 p.c. alcohol, evaporate the clear solution to dryness, dissolve in water, filter, and determine the nitric acid by Schlössing's method. For the determination of mark and cellulose, a segment of the root is reduced to pulp by rubbing on a grater; the pulp is then weighed, pressed in a cloth, the solid matter treated with water, again pressed, and the extraction with water continued as long as soluble matter is removed. In the case of turnips or beet the extraction of the pulp may be more conveniently performed on a vacuum filter, or by a method of Schulze described in the paper just referred to, but with roots containing starch the method given above is probably best. The insoluble matter, dried at 110° , gives the weight of crude fibre (mark), from which (in the case of turnip or beet) the percentage of sap in the root can be reckoned. The percentages of sap and mark are also often ascertained by Grouven's method, in which water is determined in a portion of filtered, undiluted sap, and also in the original root, and the calculation made according to the formula: $x = \frac{a \times 100}{b}$,

in which a is the percentage of water in the root, b that in the sap, and x the percentage of sap in the root. This method is the only one that will yield the percentage of sap accurately in the case of roots containing starch. To determine cellulose, the crude fibre must be boiled with a dilute solution of soda to remove pectose, &c.; in roots containing no starch, boiling with dilute sulphuric acid may probably be omitted. See determination of fibre, *FODDER PLANTS* (p. 532). Sugar is determined in the watery extract of the pulp, or in the undiluted sap; if in the latter, the percentage of sap in the root must be ascertained by one of the methods already given. In the case of sugar-beet the best and speediest method of determining sugar is with the polariscope. A weighed quantity of the expressed sap is placed in a measured flask, treated with basic lead acetate, and water added to the mark, the whole well shaken and filtered. The tube of the polariscope is filled with the clear colourless filtrate, and an observation made. The reading furnished by the instrument expresses at once the percentage of cane-sugar in the sap. As the sap forms very uniformly 96 p.c. of ripe sugar-beet, this proportion is often assumed, and the percentage of sugar in the root calculated on this basis. The weight of sap to be taken, and the amount of its dilution, are fixed quantities, which depend on the kind of polariscope employed. For further information, see iii. 674, v. 471. In roots, as carrots, containing invert-sugar, Fehling's method may be employed. The sap is boiled and filtered, and the filtrate concentrated with some sulphuric acid to complete the inversion of the sugar. For further details see ii. 864. Starch may be approximately determined in carrots and parsnips by mixing the pulp with water, squeezing through a piece of fine linen, and repeating the operation till the water runs clear. The washings are then made alkaline with a little caustic soda, and allowed to stand. The deposited starch is collected, dried, and weighed.

R. W.

ROSANILINE, $C^{20}H^{15}N^3$. On the change of colour produced in rosaniline solutions by heat, see *LIGHT* (p. 747).

Decomposition by Water (Liebermann, *Deut. Chem. Ges. Ber.* v. 144; vi. 951).—Rosaniline and its salts are scarcely attacked by water at 220° ; but if the heating be continued for several hours at 235° , the tube after cooling is found to contain a wine-red liquid, considerable quantities of red needle-shaped crystals, ammonia (sal-ammoniac when the hydrochloride is operated on), a small quantity of resin, and phenol. The cold-filtered liquid gives off ammonia on evaporation, and deposits colourless crystals which gradually turn red. These crystals dissolve in boiling water and in alcohol, forming red solutions from which the compound separates in red needles having the composition $C^{20}H^{15}NO^2.H^2O$. This compound behaves like a weak acid, dissolves with cherry-red colour in ammonia, and is reprecipitated on neutralisation, but an excess of hydrochloric acid redissolves a large portion of the precipitate. Reducing agents convert it into a colourless substance. When the residue in the digestion-tube is washed with cold water and then exhausted with boiling water, the water on cooling deposits red needle-shaped crystals, part of which dissolves with red colour in ammonia, while the greater portion remains undissolved on the filter. The compound thus obtained may be recrystallised in the same way as the preceding, and gives, by analysis, numbers leading to the formula, $C^{20}H^{15}N^3O.H^2O$. It exhibits basic

properties; its solution in hydrochloric acid is precipitated by alkalis, and yields an oily compound with platinic chloride. It melts at 176°.

If the tubes are heated to 245°, the reaction appears to proceed in the same way; the resulting crystals, however, are not red, but yellow or colourless; and the crystals of both kinds thus obtained give by analysis the same numbers as the two corresponding kinds of red crystals, with the exception of a few tenths more per cent. of hydrogen. The yellow compounds are therefore the leuco-compounds of the red; the latter likewise exhibit partial reduction.

The following are regarded by Liebermann as the most appropriate constitutional formulae for rosaniline and leucaniline:

The reaction of rosaniline with water proceeds in a totally different manner when a little hydrochloric acid is added to the water. In this case at 240° the rosaniline salt is completely resolved into aniline and toluidine.

When rosaniline is heated with water in a copper digester to 270° a large quantity of phenol is formed, which may be got rid of by boiling the product with steam. The residuum contains carbonaceous matter and a compound containing no nitrogen, together with nitrogenous bodies. The latter are removed by boiling with water, and heating the crystals which separate out from the filtrate with crude hydrochloric acid, which dissolves only the nitrogen-compounds. The residuum crystallises from boiling water in pointed plates melting at 200°, and from alcohol in small plates. It dissolves in alkalis without colour, and with sodium-amalgam and water it gives a red solution, which soon becomes colourless. This compound contains C = 72.5; 72.6; 73.3; 73.4; and H = 5.0; 5.3; 5.8, or less than required for the formula $\text{C}^{20}\text{H}^{14}\text{O}^2 + \text{H}^2\text{O}$; it does not change its composition at 170°. It has nothing in common with rosolic acid or with hydrosolic acid. By heating it with hydriodic acid to 160°, or with hydrochloric acid to 200°, it is resolved into phenol and cresol. Acetic anhydride converts it at 160° into a compound crystallising from alcohol in needles melting at 156°, and containing C = 68.25 and H = 5.21. Heated with phosphorus pentachloride containing trichloride to 170°, it yields the compound $\text{C}^{20}\text{H}^{12}\text{Cl}^2\text{O}^2$, crystallising from alcohol in colourless plates melting at 137°. This last compound is not changed by heating it with alcoholic potash, and gives up only part of its chlorine when boiled with sodium-amalgam.

ROSE OIL. See OILS VOLATILE (p. 872).

ROSIN OIL. On the preparation and purification of this oil, and its use as a lubricator for machinery, and in the preparation of railway and waggon grease, see *Dingl. pol. J.* cccv. 246; ccvii. 237; *Chem. Soc. J.* [2], xi. 304, 1175.

ROSOCYANIN. See CURCUMIN (p. 404).

ROSOLIC ACID. This name has been somewhat vaguely applied to a number of red compounds obtained from phenol by various reactions, but it is now restricted to the product, also called *pseudocoralin*, obtained by treating phenol with a mixture of oxalic and sulphuric acids (1st Suppl. 999, and p. 391 of this volume). Caro n. Wanklyn assign to it the formula $\text{C}^{20}\text{H}^{10}\text{O}^4$. H. Fresenius regards it as $\text{C}^{20}\text{H}^{12}\text{O}^{10}$.

Fresenius attributes the formation of rosolic acid on heating a mixture of oxalic acid and phenol with sulphuric acid, to the action of nascent carbon monoxide on sulphophenic acid; but, according to Prud'homme (*Bull. Soc. Chim.* [2], xix. 359), the presence of a conjugate phenol-acid is not essential, the sulphuric acid acting merely as a dehydrant. In fact, on replacing the sulphuric acid by boric, arsenious, or arsenic acid, or even on heating a mixture of phenol and dehydrated oxalic acid, rosolic acid is formed; moreover, the colouring matter is not produced on heating a mixture of crystallised oxalic acid and phenol. Prud'homme infers from these results that rosolic acid is a product of the direct action of nascent carbon monoxide on phenol, and that its constitution is correctly expressed by the formula $\text{C}^6\text{H}^4\text{COH.OH}$, suggested by Kolbe (1st Suppl. 391).

Fresenius purifies rosolic acid by converting it into a magnesium salt; dissolving this salt in hot water, precipitating with sal-ammoniac, repeating this treatment till the aqueous solution of the magnesium salt is no longer coloured darker by an alkaline solution of potassium ferricyanide, and finally decomposing the magnesium salt with solution of hydrochloric acid, and crystallising the precipitate from alcohol or glacial acetic acid. The crystals are red by transmitted and green by reflected light, melt at 15.6° to a mass having the colour of cantharides, and give off water at a still higher temperature. By fusion with potash, rosolic acid is converted into a resinous mass, which is

resolved by sulphuric acid into a flocculent and a resinous mass, both of which are dissolved by ether and by alkalis. An alkaline solution of potassium ferricyanide added to the alkaline solution of the decomposition-products, gives rise to the reproduction of rosolic acid. Iron and acetic acid convert rosolic acid into leucorosolic acid. Strong nitric acid forms nitro-products, one of which is crystalline. When rosolic acid is distilled with potash, diphenyl appears to be formed, together with other products.

Rosolic acid is recommended by Schultze a. Märker (*Zeitschr. anal. Chem.* ix. 334) as an indicator in the estimation of carbonic acid by Pettenkofer's method (absorption of the carbonic acid by lime- or baryta-water of known strength, and subsequent titration with oxalic or hydrochloric acid). The rosolic acid is dissolved in alcohol and carefully neutralised with potash. A few drops of this tincture, added to the baryta- or lime-water, produce the deep red colour of barium or calcium rosolate, which is changed to a faint yellow by the slightest excess of acid. According to Schultze a. Märker this change of colour is more delicate than that afforded by litmus or turmeric.

Rosolic acid has been also recommended as an indicator in nitrogen determinations, when the evolved ammonia is absorbed by standard sulphuric acid; but in this case it does not give equally good results, since the colour which the liquid generally acquires from absorption of organic matter greatly interferes with the delicacy of its indications.

ROTATING FURNACE (Siemens'). See IRON METALLURGY (p. 702).

RUBIDINE, $C^{111}H^1N$. This base has been detected in tobacco-smoke (see TOBACCO).

RUBIDIUM. This metal has been found in the ash of beet-root. To separate it, the mother-liquor left in preparing saltpetre from the ash of beet-root molasses is mixed with saw-dust and deflagrated, the charred mass exhausted with water, the solution evaporated to 1.317 sp. gr., and the sulphates and chlorides allowed to crystallise out. This second mother-liquor is mixed with hydrochloric acid, heated, filtered from precipitated sulphur, &c., and boiled with nitric acid till all iodine and bromine are expelled. The rubidium is now precipitated from the diluted solution by platinum tetrachloride, and separated in the usual way.

Direct experiment shows that one kilogram of the beet-ash of Northern France contains 1.75 grm. of rubidium chloride, and that the rubidium chloride is to the sodium chloride and potassium chloride as 1 to 126 and 331 (Pfeiffer, *Arch. Pharm.* [2], cl. 97; *Dingl. pol. J. cervi.* 498).

RUE OIL. The principal constituent of this oil is methyl-nonyl ketone, $C^{11}H^{20} = CH^3.CO.C^9H^{19}$ (p. 808).

RUFICARMIN.

RUFICOCOIN.

} See COCHINEAL (pp. 367, 368).

RUFIGALLIC ACID, $C^{11}H^4O^8$.—This compound, which Robiquet obtained by heating gallic acid with sulphuric acid to 140° , is more easily produced by the action of sulphuric acid at 80° – 90° on digallic acid, $C^{11}H^{10}O^8$, from which it differs by H^2O ; further, by the action of sulphuric acid on tetracetyl-tannic acid, $C^{14}H^4(C^2H^3O)^4O^8$; similarly from ethyl gallate, $C^8H^7(OH)^3.COOC^2H^5$, with separation of alcohol, and from ethyl triacetyl-gallate, $C^8H^4(C^2H^3O)^3.COOC^2H^5$, with separation of ethyl acetate. Sulphuric acid acts therefore, in the formation of rufigallic acid, on the carbonyl groups, and as rufigallic acid no longer exhibits the properties of an acid, we may infer that it is nothing more than the anhydride of digallic acid:

Rufigallic acid can in fact take up four atoms of acetyl, forming the compound $C^{14}H^4(C^2H^3O)^4O^8$, which crystallises from boiling glacial acetic acid in small yellow or greenish-yellow prisms, sparingly soluble in alcohol even at the boiling heat. When treated with potash, these crystals turn yellow, and afterwards violet (H. Schiff, *Deut. Chem. Ges. Ber.* iv. 967), (see TANNIC ACID).

S

SABADILLA. The alkaloids of sabadilla seeds have been examined by H. Weigelin (*Chem. Centr.* 1872, 220). The pounded seeds, freed from their capsules, are boiled with very dilute sulphuric acid, and the extract is treated with three times its volume of 80 p.c. alcohol to precipitate mucilaginous matters; after evaporation of the alcohol, the boiling solution is precipitated by ammonia, whereby a resinous mass is obtained containing veratrine, which may be purified by solution in ether, evaporation, solution of the residue in alcohol, and repeated precipitation by water. The ammoniacal filtrate is agitated with amyl alcohol, the extract evaporated, the residue dissolved in alcohol and precipitated with water, and the precipitate purified by animal charcoal: finally, the concentrated solution of the bases is precipitated by ammonia. Ether extracts from the precipitate a bright-red substance, subatrine, $(C^{11}H^{10}N^2O)^+$, and leaves behind sabadilline, $C^{11}H^{10}N^2O^{12}$, to be purified by solution in boiling water. The latter alkaloid is not absolutely insoluble in ether, and is not carbonised by sulphuric acid, but gives a yellow solution, becoming blood-red, and, finally, carmine-coloured; ammonia does not precipitate it from its salts, and alkaline carbonates give a turbidity only with boiling concentrated solutions (1 to 5). It is soluble in benzene, amyl alcohol, petroleum spirit, and chloroform, and crystallises from benzene, but not from water or alcohol; it does not produce sneezing or emetic action in frogs, but accelerates the action of the heart. Its gold salt, $(C^{11}H^{10}N^2O^{12} \cdot 2HCl \cdot Au^2Cl^6)$, is amorphous; its hydrochloride and sulphate are gummy.

Subatrine much resembles sabadilline in properties; it gives two compounds with gold chloride, one amorphous = $C^{11}H^{10}N^2O^7 \cdot 2HCl \cdot Au^2Cl^6$, the other crystalline, = $5(C^{11}H^{10}N^2O^7 \cdot 2HCl) \cdot 11Au^2Cl^6$.

Veratrine can be obtained in two modifications, one of which is readily soluble in water. Weigelin finds the quantity of nitrogen contained in this alkaloid to be much less than that previously assigned to it, and represents it by the formula $C^{12}H^{10}N^2O^{12}$ (compare v. 996).

SACCHARIMETRY. See SUGAR.

SACCHARUMIC ACID, $C^{14}H^{18}O^{11} = C^{14}H^{18}O^8 \cdot 3H^2O$ (H. Reichardt, *Vierteljahrsschrift pr. Pharm.* xix. 384, 503). An acid formed, together with glucic acid (p. 556), by the action of baryta on grape-sugar. A mixture of baryta-water and grape-sugar deposits, when heated, a barium-compound, which is likewise obtained when the brown mass formed by melting grape-sugar with barium hydrate, is diluted with water as long as a precipitate forms. To obtain the acid contained in this precipitate free from glucic acid, the precipitate is suspended in water, and dilute sulphuric acid is added in quantity sufficient to produce a slight acid reaction. The filtrate mixed with lead acetate yields a precipitate of lead saccharumate; and by decomposing this precipitate with hydrogen sulphide, evaporating the filtrate at a gentle heat, and drying at 80° , saccharumic acid is obtained as a yellow-brown powder having an astringent taste, easily soluble in water and in alcohol, sparingly in ether. Its solution when exposed to the air gradually becomes darker, and deposits brown substances. Alkalis colour the acid solution darker. The acid decomposes the carbonates of calcium and barium, forming acid salts, like $C^{14}H^{18}BaO^{11}$. Lime-water produces a slight, baryta-water a more copious precipitate of the salt, $C^{14}H^{18}Ba^2O^{11} + 5H^2O$. Cupric salts give with neutral solutions a grey-brown precipitate having the composition $C^{14}H^{18}Cu^2O^{11} + 3H^2O$, which dissolves easily in free alkali and acid, and decomposes readily when heated. The precipitates thrown down from a neutral solution of the acid, by neutral and basic lead acetate, are respectively $C^{14}H^{18}Pb^2O^{11}$ and $C^{14}H^{18}PbO^{11}$.

SAFRANINE, $C^{11}H^8N^4$ (Hofmann a. Geyger, *Deut. Chem. Ges. Ber.* v. 526). A red dye prepared commercially, according to Mène (*Chem. News*, xxv. 215), by treating aniline with nitrous acid and arsenic acid successively, the higher-boiling portions of aniline oil being best adapted for the purpose. Hofmann a. Geyger find that this process yields but a small quantity of safranine, mixed with a large amount of secondary products, and that the preparation of safranine succeeds best when chromic acid is used as the oxidising agent instead of arsenic acid. Safranine cannot, however, be prepared from pure aniline or solid toluidine, or a mixture of the two, but it can be obtained from liquid toluidine boiling at 198° . Safranine appears therefore to be a derivative of toluidine, and its formation may be explained by the equations:

Safranine is met with in commerce in the form of a paste, and of a yellowish-red powder, which contains the hydrochloride of the base mixed with calcium carbonate and common salt. On boiling this with water, and allowing the solution to cool, a crystalline substance separates, which, after repeated recrystallisation from water, will be found to leave no residue when burnt. It, however, loses hydrochloric acid by these operations, and becomes more soluble, so that the addition of hydrochloric acid to the mother-liquors causes a further separation of the crystalline hydrochloride.

The free base is obtained by decomposing the solution of the hydrochloride with silver oxide, and evaporating the deep red liquid. On cooling, red-brown crystals are deposited, which closely resemble the hydrochloride in appearance. Safranine dissolves easily in water and in alcohol. Dried at 100° , it acquires a faint greenish metallic lustre. The addition of hydrochloric acid to the aqueous solution of the base precipitates safranine hydrochloride.

The most characteristic reaction of safranine is that when strong hydrochloric acid, or, better, sulphuric acid, is gradually added to its solutions, the colour changes first to a fine violet, and then successively to blue, dark green, and light green. On diluting the solution, the same changes of colour are observed in reverse order.

Safranine Hydrochloride, $C^{21}H^{20}N^4.HCl$.—To obtain the normal hydrochloride, it is necessary to acidify the boiling solution of the salt with hydrochloric acid. It forms thin reddish crystals, which are soluble in water and in alcohol, especially when heated. It is insoluble in ether and in a concentrated solution of salt. Both the aqueous and alcoholic solutions have an intensely yellowish-red tint. The addition of ether to the latter solution causes the precipitation of the hydrochloride.

The *platinochloride*, $2(C^{21}H^{20}N^4.HCl).PtCl_4$, is obtained by precipitating a warm solution of the hydrochloride with excess of platinum chloride, and washing the precipitate with dilute hydrochloric acid. It is a crystalline yellowish-red powder, almost insoluble in water, alcohol, and ether.

Safranine Hydrobromide is precipitated in microscopic needles on adding hydrobromic acid to a solution of the base. It is almost insoluble in cold, but soluble in boiling water. The addition of bromine to a solution of the hydrochloride causes a precipitate which, when recrystallised from water, yields needles having a metallic green lustre. The *hydriodide* is similar to the hydrobromide.

Safranine Nitrate, $C^{21}H^{20}N^4.HNO_3$.—On adding an excess of dilute nitric acid to a hot aqueous solution of the free base, and leaving the liquid to cool, the nitrate separates in fine red-brown needles, which are difficultly soluble in cold, but readily in hot water. It is decidedly less soluble than the hydrochloride.

Safranine Sulphate is a moderately soluble salt, precipitated by the addition of sulphuric acid to a concentrated solution of the base. On warming the liquid it redissolves, and separates again in fine needles on cooling. The *oxalate* is very similar, but somewhat less soluble. The *acetate* is very soluble.

Safranine Picrate, $C^{21}H^{20}N^4.C^6H^3(NO_2)_3O$.—When picric acid is added to a dilute solution of safranine hydrochloride or nitrate, the picrate is precipitated in brownish-red needles which are insoluble in water, alcohol, or ether.

SAHLITE. *Calcio-magnésio-ferruginous Augite*.—This mineral occurs, together with graphite, in some of the dense limestones imbedded in the mica- and hornblende-slate of Valpellina in the Pennine Alps. The augite forms rounded grains having a fused appearance, generally from $\frac{1}{2}$ to 1 mm. in size, and of a bluish colour on the outside, whitish-grey within. Some of these grains exhibit crystalline faces, namely, those of the vertical prism of augite, and of the ortho- and clinopinacoid. They exhibit distinct cleavage in two directions parallel to the faces of the vertical prism, indistinct, parallel to the clinopinacoid. Before the blowpipe the mineral melts easily and with violent intumescence. Sp. gr. = 3.320. Loss by ignition 0.14 p.c. Analysis gave:

SiO ²	CaO	MgO	FeO	AlPO ⁴	
54.02	24.88	13.62	8.07	0.20	= 100.60,

which, neglecting the alumina, agrees nearly with the formula $(\frac{1}{2}FeO.\frac{1}{2}MgO.\frac{1}{2}CaO)SiO_2$ or $FeMg^2Ca^4Si^6O^{24}$ (calc. 53.57 SiO², 25.00 CaO, 13.39 MgO, 8.04 FeO).

SALANT. This name is applied, in the Departments bordering on the Mediterranean, to a thin saline incrustation, which in some places completely covers barren lands, and in others forms isolated barren spots in the fertile soil. These spots consist essentially of sodium chloride mixed with 6 to 10 p.c. calcium sulphate. The analysis of the soils on which they occur gave in 100 pts.—(1) on the surface; (2) 30 cm. deep; (3) from a salant spot in the midst of a cultivated soil, which close to it con-

tained only 0.0002 of the salts. The samples examined were from Agde, in the Department of Hérault:

	NaCl	CaSO ⁴	MgSO ⁴
(1)	6.163	0.176	0.228
(2)	0.761	0.051	0.129
(3)	0.845	—	0.300

(E. P. Bérard, *Compt. rend.* lxxiii. 1155).

SALICYLIC ACID, $C^6H^4O^2 = C^6H^3OH.CO^2H$. *Formation and Constitution.*—On the formation of salicylic acid from sulphobenzoic acid, and from orthotoluene-sulphonic acid, and the proofs that it belongs to the ortho- (1 : 2) series, see pp. 134, 135.

Hübner (*Ann. Chem. Pharm.* clxii. 71) finds that when ordinary bromobenzoic acid (purified by several crystallisations and melting at 155°) is fused with potassium hydrate, salicylic acid is formed as well as oxybenzoic acid; whereas the latter, which is the analogue of ordinary bromobenzoic acid, might be expected to be the sole product. As, however, salicylic acid is known to be formed by the action of potassium carbonate on phenol, its production in this case may be supposed to take place in the manner represented by the following equations, the bromobenzoic acid being first converted into bromobenzene, then into phenol, and the phenol into salicylic acid:

Preparation.—The preparation of salicylic acid from wintergreen oil being very expensive when large quantities are required, Kolbe (*J. pr. Chem.* [2], x. 89) has endeavoured to improve the method of obtaining it from phenol, devised by himself and Lautemann some years ago (v. 153).

Sodium-phenol is prepared by dissolving crystallised phenol in a strong solution of commercial soda (in the exact proportions of the molecular weights, as an excess of phenol causes the product to be highly coloured, and diminishes the yield of salicylic acid), evaporating to dryness in iron vessels, and finally heating the pasty mass over a flame, stirring all the while. The sodium-phenol, being very hygroscopic, should be placed when hot in stoppered bottles, as moisture diminishes the yield of acid. The sodium-phenol is then heated in a retort to 100°, a slow stream of carbonic anhydride is passed through the apparatus, and the temperature after many hours is allowed to rise to 180°. Phenol then distils over, till the temperature rises to 220°–250°, the operation being completed when no more phenol passes over at this temperature. It was supposed that the reaction would take place as follows:—

but as the retort contained basic sodium salicylate, and phenol distilled over, the process evidently takes place according to the following formulæ:

which is the result of two simultaneous reactions:

On decomposing the basic salt with hydrochloric acid, the salicylic acid is separated, and can be purified by dissolving it in etherated alcohol, boiling with soda, and again decomposing by acid.

Salicylic acid is also formed, but in smaller quantities, when barium or calcium phenol is used. Potassium-phenol gave various results, at one time salicylic acid, at another time paraoxybenzoic acid. Those irregularities were at first considered to be due to the presence of sodium in the potassium used, but they are now attributed to the influence of the heat at which the operation is performed. To determine this two series of experiments were instituted. Potassium-phenol, prepared in the same manner as the sodium-phenol, when heated for four hours at 100°, and subjected to the action of carbonic anhydride, yielded but a small amount of acid, consisting wholly

of salicylic acid. When it was heated to 135°, and carbonic anhydride then passed through it, the temperature being allowed to rise to 145°, phenol was produced, and a large amount of salicylic acid, but no paraoxybenzoic acid. But when carbonic anhydride was allowed to act first at 170°, and the temperature then raised to 200°–210°, phenol distilled in its proper proportions, and a large amount of paraoxybenzoic acid was formed without a trace of salicylic acid.

In other experiments carbonic anhydride was passed through heated phenol, and when the temperature had risen to 130°, potassium was added till it rose to 150°. When the equivalent quantity of potassium had been added, the product yielded pure salicylic acid. Another portion of phenol saturated with potassium yielded a distillate of phenol at about 200°, and the retort contained a considerable quantity of paraoxybenzoic acid free from salicylic acid. If sodium-phenol be treated with carbonic anhydride at 240°–280° for four hours, pure salicylic acid is produced without a trace of paraoxybenzoic acid.

From a mixture of salicylic and paraoxybenzoic acids, the greater part of the salicylic acid may be separated in the form of a sparingly soluble basic calcium salt, by mixing the aqueous solution of the acids with excess of milk of lime. A more exact method of separation, however, is to dry the mixture of acids at 100° and digest it in boiling chloroform, which dissolves the salicylic acid easily, and takes up but little of the paraoxybenzoic acid (Kolbe).

On the Heat of Combination of Salicylic acid with Bases, see HEAT (p. 62).

Physiological action.—Given in large doses (6 grams in two days) salicylic acid produces singing in the ears, and passes out in the urine, partly as salicylic acid, partly unchanged; it may also be detected in 2 hours, and even after 20 hours in urine, although the dose may be only 0.3 gram. Owing to the fact that it is easily decomposed into phenol and carbonic anhydride, it acts antiseptically, preventing fermentation and decomposition, and may therefore be applied to the preservation of meat. For this latter purpose it is preferable to phenol, as it is tasteless, or nearly so. Neither paraoxybenzoic nor oxybenzoic acid acts antiseptically. Salicylic acid has also been applied to the dressing of wounds, and has been found to work very satisfactorily, aiding granulation, &c., and preventing fever (Kolbe, *loc. cit.*)

Action of Phosphorus oxychloride.—With this reagent, salicylic acid yields condensation-products. The portion of the product insoluble in hot water contains the compounds:

The former crystallises from boiling alcohol, the latter is a solid brittle resin.

Nitrosalicylic acid is likewise attacked by phosphorus oxychloride (H. Schiff, *Deut. Chem. Ges. Ber.* iv. 969).

Iodosalicylic Acid. Hlasiwetz and Weselsky (*ibid.* v. 380) have succeeded in replacing part of the hydrogen in salicylic acid and its isomerides by iodine, by the process which they formerly applied to the formation of iodophenols (*1st Suppl.* 910), viz. the action of iodine in presence of mercuric oxide. Salicylic, oxybenzoic, and paraoxybenzoic acid when thus treated exhibit different degrees of capability of taking up iodine in exchange for hydrogen.

Nitrosalicylic Acids. When salicylic acid is nitrated, not only is ordinary nitrosalicylic acid formed, but also two more soluble isomerides, one of which crystallises in long colourless needles melting at 124°. This modification dissolves sparingly in cold water, readily in hot water and alcohol, and gives, with ferric chloride, a reddish-blue colour. The *potassium salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\text{OK}.\text{CO}^2\text{K}$, crystallises from hot water in long yellow needles. The *magnesium salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\text{O.CO}^2\text{Mg} + 3\text{H}^2\text{O}$, forms yellow needles which readily dissolve in hot water. The *barium salt*, $(\text{C}^6\text{H}^4(\text{NO}^2)\text{OH.CO}^2)^2\text{Ba}$, crystallises from a hot aqueous solution in scales, and from a dilute in slender needles. The *lead salt*, $\text{C}^6\text{H}^4(\text{NO}^2)\text{O.CO}^2\text{Pb}$, is a yellow precipitate. The *silver salt*, $\text{C}^6\text{H}^4\text{NO}^2\text{OH.CO}^2\text{Ag}$, is readily soluble and forms glistening brownish needles. The second isomeric acid remains in the mother-liquor of the barium salt of the first, and crystallises in long colourless needles melting at 218°. Its *barium salt*, $(\text{C}^6\text{H}^4(\text{NO}^2)\text{OH.CO}^2)^2\text{Ba} + 4\text{H}^2\text{O}$, forms hard, light yellow, compact crusts (L. B. Hall, *Deut. Chem. Ges. Ber.* vii. 1820).

SALICYLIC ALDEHYDE, or SALICYLOL, C}^6\text{H}^4\text{O}^1. This compound, treated with phosphorus oxychloride, yields a purple-red, non-crystallising product which dissolves in alkalis with splendid violet colour (Schiff).

SALICYLIC ANHYDRIDES. Several anhydrides of salicylic acid have been described by Gerhardt (v. 160) and by Kraut (1st Suppl. 1007). Schiff (*Ann. Ch. Pharm.* clxiii. 218) prepares salicylide, $C^6H^4O^2$, and tetrasalicylide, $C^{24}H^{16}O^8$, by the action of phosphorous oxychloride on salicylic acid. This acid when heated dissolves easily in the oxychloride, with abundant evolution of hydrochloric acid. At the end of the reaction the liquid is decanted from the separated metaphosphoric acid, the excess of oxychloride is distilled off, and the residue is decomposed, while well cooled by throwing in lumps of ice. The mass, which soon solidifies, is boiled with water to remove unaltered salicylic acid, and treated several times with boiling alcohol. The alcoholic solution yields, by repeated crystallisation, large spherical groups of shining needles which shrink up very much when dried. These crystals consist of salicylide:

The reaction takes place in the manner represented by the equation:

Salicylide is insoluble in water, does not give the purple reaction with iron salts, or a precipitate with lead salts, and is not attacked by acetyl chloride. It melts for the most part at 195° - 200° , but decomposes partially at the same time, so that the whole does not become liquid till heated to 220° - 225° . By boiling with potash it is reconverted into salicylic acid.

The portion of the original product which is nearly insoluble in boiling alcohol, forms a white hard resinous mass, insoluble in water, and only slightly soluble in alcohol, ether, and benzine, even at the boiling heat. The results of its analysis agree very well with the formula $C^{24}H^{16}O^8 = 4C^6H^4O^2 - 3H^2O$, which is that of Kraut's tetrasalicylic acid; Schiff calls it tetrasalicylide. It softens at 205° , is perfectly fluid at 230° , and decomposes at about 250° . Strong sulphuric acid dissolves it with yellow colour, and water partly precipitates it from the solution unaltered, partly converts it into salicylic acid. When heated with strong sulphuric acid it forms sulphosalicylic acid.

As tetrasalicylide exhibits no iron reaction, and does not yield any acetyl derivative, it may be regarded as the first anhydride of disalicylic acid:

To Gerhardt's salicylic anhydride, which Kraut designates as *Salicylo-salicylic acid*,

Schiff assigns the formula, $C^6H^4 \left\{ \begin{array}{c} \text{COOH} \\ O \\ \text{COOH} \end{array} \right\} C^6H^4$, as otherwise its formation from aceto-

salicylic acid should be attended with the elimination of an atom of acetyl in the form of acetic acid, and the presence of a phenolic hydroxyl should give rise to the well-known iron reaction, which is not the case.

The existence of Kraut's *trisalicylo-salicylic acid* is doubted by Schiff, inasmuch as the more exact calculation of the analyses given by Kraut does not yield very accordant results. Kraut, on the other hand (*Ann. Ch. Pharm.* clxv. 159), upholds the existence of the acid in question, and the correctness of the analytical numbers which he obtained.

SALIGENIN and SALIRETIN. Kraut (*Ann. Ch. Pharm.* cl. 123) prepares saliretin by drenching finely-pulverised salicin with 10 pts. fuming hydrochloric acid of sp. gr. 1.125, warming the solution with agitation, and then heating it to 80° , whereupon part of the saliretin produced separates as a pulverulent precipitate. The precipitation is completed by pouring the pasty mass into a large quantity of water; the precipitate is washed till free from chlorine, and dissolved in moderately dilute spirit, a small quantity of gelatinous matter then remaining undissolved; and the saliretin is separated by pouring the filtrate into a large quantity of salt water. It then falls down quickly in curdy flocks, whereas pure water merely renders the alcoholic solution turbid.

Saliretin thus prepared is a yellowish or reddish-yellow powder. After drying over oil of vitriol, it gives off no more water at 100° or even at 200° , but cakes together and turns brown at the latter temperature. It is soluble in aqueous alcohol, and if its preparation has been conducted at the temperature above mentioned, it likewise dissolves almost completely in absolute alcohol. If, on the other hand, salicin has been decomposed by hydrochloric acid at a temperature not exceeding 40° , the solution of the product in aqueous alcohol yields, on addition of absolute alcohol, a precipitate, which however does not differ from saliretin either in composition or in properties.

Saliretin is commonly represented by the formula C^7H^5O or $C^{14}H^{10}O^2$; but Kraut's analysis leads to the formula $C^{14}H^{10}O^2$, originally suggested by Moitessier (*Jahresb. f. Chem.* 1866, 677), who regarded saliretin as related to saligenin, in the manner as an ether to a monatomic alcohol:

Kraut, however, regards saliretin, not as the ether of saligenin, but as *saligeno-saligenin*:

a compound analogous to salicylo-salicylic acid (1st Suppl. 1007):

Saliretin is likewise precipitated by salt water from its alkaline solution, and the precipitate, after continuous washing with the same liquid, contains, after deduction of sodium chloride, a quantity of soda less than sufficient to form a saturated or half-saturated sodium-compound.

Piria found that saliretin, when oxidised by chromic acid, does not yield salicylol; and Kraut finds that, when oxidised by potassium permanganate, it does not yield either salicylol or salicylic acid, or in general any well-characterised product of decomposition.

A substance called saliretin, which Gerhardt prepared by the action of sulphuric acid on saligenin, exhibits the composition of trisaligeno-saligenin, $C^{21}H^{15}O^3 = 4C^7H^5O^2 - 3H^2O$; some resinous products prepared by Beilstein & Seelheim (*Jahresb.* 1861, 765) from saligenin, by the action of acetic anhydride or ethyl iodide, appear to consist of *heptasaligeno-saligenin*, $C^{49}H^{35}O^7 = 8C^7H^5O^2 - 7H^2O$ (Kraut).

Action of the Acetyl-derivatives of Sugars on Sodium-saligenin.—Acetyl-glucose and sodium-saligenin, heated together in presence of alcohol or benzene, yield a small quantity of a substance which forms glucose and saliretin when boiled with dilute sulphuric acid. This substance is obtained pure by evaporation to dryness, solution in water, precipitation by lead acetate, and decomposition by hydrogen sulphide; and, finally, by evaporation to dryness in a vacuum, there is obtained an amorphous, yellowish, brittle mass, soluble in water and in alcohol. The greater part of the substances employed, however, react differently, producing acetosaliretin and sodium glucinate; the former of these, which, by saponification, yields saliretin and sodium acetate, is likewise formed by the action of acetic anhydride on saliretin (Schützenberger, *Ann. Chim. Phys.* [4], xxi. 235).

Diacetosaccharose and sodium-saligenin, heated in an open vessel with absolute alcohol, also form a small quantity of a glucoside which splits up into glucose and saliretin; the greater portion of the substance, however, is converted into acetosaliretin, and the sodium salt of an acid very similar to glucinic acid, which may be termed *saccharinic acid*. This sodium salt, $C^{12}H^{10}NaO^3$, separates from boiling absolute alcohol in small, white crystals; it is very soluble in water, gives with basic lead acetate a precipitate soluble in excess of the acid, and yielding the acid itself by decomposition with hydrogen sulphide; the acid forms a very sour syrup (Schützenberger).

The lead precipitate obtained by treating saligenin with lead acetate also yields, when heated with an aqueous solution of acetyl-glucose or acetyl-saccharose, a considerable quantity of a glucoside, which, when treated with acids, splits up into saliretin and glucose (Schützenberger).

SALINE SOLUTIONS. On the Capillarity of Saline Solutions, and its relation to their Density, see pp. 243, 244.

On the Electrolysis of Saline Solutions, see ELECTRICITY (pp. 460-462).

On the Specific Heat of Saline Solutions, see HEAT (pp. 596-601).

Solidifying Points of Saline Solutions.—L. G. de Coppet (*Ann. Chim. Phys.* [4], xxii. 366-406; xxv. 502-553; xxvi. 98-121) has made elaborate experiments on the lowering of the freezing point and point of maximum density of saline solutions below those of pure water, and has applied the results to the determination of the chemical constitution of the solutions. The experiments of Rüchhoff on the freezing of water from saline solutions (iii. 80; also *Pogg. Ann.* cxiv. 63; cxvi. 55; *Jahresb. f. Chem.* 1861, 56; 1862, 23) have shown that if M denotes the amount of anhydrous salt in 100 pts. of water, and E the lowering of the freezing point of the solution below 0° , the ratio $\frac{E}{M}$ is sometimes constant, sometimes increases with the increase of

M ; and, assuming that, in the former case, the salts are present in the solutions in the anhydrous state, and in the second, in combination with a certain number of molecules, r , of water of hydration, it follows that if M_r denotes the amount of this hydrate in 100 pts. of water, the ratio $\frac{E}{M_r}$ is constant. De Coppet recognises a third case, in

which $\frac{E}{M}$ decreases with increase of M , and he further finds that in many cases in

which $\frac{E}{M}$ increases, no value of r can be found for which the ratio $\frac{E}{M_r}$ is constant.

To explain these two cases, De Coppet supposes that, in the solutions in question, a partial decomposition (dissociation) of the salt takes place, in such a manner that in many cases the dissociation extends only to the state of hydration of the salt, while in others the salt itself is modified by the action of the water, so that the solution contains a mixture of compounds, the proportion between which varies with the concentration and the temperature. This decomposition of a hydrate dissolved in water may be compared with that of a hydrated salt in a limited space filled with aqueous vapour (1st Suppl. 425), the quantity of water combined with a dissolved salt depending, not only on the temperature, but likewise on the degree of concentration of the solution.

Denoting by E and D the depressions of the freezing point and of the maximum density of a solution, and by M the amount of anhydrous salt in 100 pts. of water, De Coppet draws from the whole of his investigation the following conclusions:

1. If the ratios $\frac{E}{M}$ and $\frac{D}{M}$ are both constant between given limits of pressure and temperature, it may be inferred that between these limits the salt is present in the solution in the anhydrous state.

2. If the ratios $\frac{E}{M}$ and $\frac{D}{M}$ increase as M increases, the solution will contain at least one compound formed at the expense of the solvent. If solutions, between certain limits of temperature and concentration, contain only one hydrate, the number of water molecules r in the latter may be calculated by the following formula established by Müldorff (*Pogg. Ann.* cxvi. 62):

$$r = \frac{100A(M't - M't')}{18MM'(t - t')}$$

in which A is the molecular weight of the salt M , and M' two different quantities of the dissolved salt, t and t' the corresponding freezing points.

3. If the ratios $\frac{E}{M}$ and $\frac{D}{M}$ decrease as M increases, the salt in the solution has probably been altered by the action of the solvent.

These conclusions, taken in their strict sense, are applicable to each particular solution only at its freezing temperature or at the point of maximum density.

The following table (p. 1070) exhibits some of the numerical results of De Coppet's experiments. The second column contains the formulae of the anhydrous salts or hydrates which are supposed to exist in the solution at the freezing point; those hydrates which are not yet known in the solid state are distinguished by an asterisk. The fourth and fifth columns exhibit the coefficients of depression of the freezing point h , referred to the unit of weight of substance dissolved in 100 pts. of water, and the depressions of the freezing point H , referred to one molecule.

From this table it appears that bodies belonging to the same molecular group exhibit nearly equal molecular depressions of the freezing point. Potash and soda are related to the group including the chlorides, bromides, and iodides of the alkali-metals; but for the group including the chlorides, bromides, and iodides of the alkali-metals and alkaline ammonia the molecular depression is not much more than half as great, whence De Coppet infers that the constitution of ammoniacal solutions differs from that of solutions of potash and soda.

A similar relation exists between the molecular weights of salts and the lowering of their temperatures of maximum density, and affords, for a large number of salts, in default of direct observations, the means of calculating the temperatures of freezing, and of the maximum density of their aqueous solutions. De Coppet, indeed, by comparing the two kinds of molecular depression, arrives at the general conclusion that for each group of the chlorides, bromides, and iodides of the alkali-metals and alkaline earth-metals, for caustic potash and soda, and probably for a large number of other bodies of corresponding chemical constitution, the molecular depression of the temperature of maximum density of aqueous solutions is nearly four times as great as the molecular freezing point depression. For that particular solution of each substance for which the freezing point coincides with the point of maximum density, both these temperatures are situated, within a few hundredths of a degree, at -1.33° .

Depression of the Freezing Points of Saline Solutions.

		Molecular weight Λ	Coefficient of depression Λ	Depression for 1 molecule $\Pi = \Lambda \cdot A$

For De Coppet's experiments on the depression of the freezing point in *solutions of mixed salts*, and for his comparison of his own results with the conclusions arrived at by Wüllner in his Memoir on the Tension of the Aqueous Vapour from Saline Solutions (iii. 95), see the original paper (*Ann. Chim. Phys.* [4], xxvi. 98).

From experiments by Rüdorff (*Pogg. Ann.* cxlv. 599), it appears that the molecular decrease of the ratio $\frac{E}{M}$ with increase of M is most strikingly exhibited in solutions of *silver nitrate*, in which it varies from 0.175° to 0.108° between $M = 4$ and $M = 62$, and of *acetic acid*, in which it decreases from 0.325° to 0.237° between $M = 2$ and $M = 62$.

Contraction accompanying the Solution of Salts.—The following observations on this phenomenon have been made by Valson (*Compt. rend.* lxxiii. 1376). For very soluble salts the contraction continually diminishes down to an imperceptible amount, as the contraction approaches its maximum.

With regard to strength of contraction, the substances examined form the following series:—1. According to the *metalloidal radicles*: Carbonates, sulphates, chlorides, nitrates, iodides. 2. According to the *metallic radicle*: Iron, zinc, copper, magnesium, strontium, barium, calcium, sodium, lead, potassium, ammonium. Hydrated salts exhibit a much smaller coefficient of contraction than the corresponding anhydrous salts, and the contraction is smaller the greater the number of molecules of water of crystallisation. Hence the chief part of the contraction appears to be completed in the formation of the crystal itself with the first molecule of crystallisation-water which the anhydrous salt takes up. Amongst anhydrous salts, those which crystallise appear to have the smallest coefficients of contraction. On the other hand, the number of molecules of crystallisation-water is greater as the coefficient of contraction referred to the anhydrous salt is higher. (See also pp. 293–304.)

Solubility and Density of Solutions of Potassium and Sodium Salts.—Page a. Keightley (*Chem. Soc. J.* [2], x. 566) have determined the density and saline contents of saturated solutions of the chloride, nitrate, and sulphate of potassium and of the nitrate and chloride of sodium at 15.6° ; also the density of each of these salts in the solid state at 15.6° , and the solubility of each in presence of one or two of the others. The solutions were prepared at the constant temperature of 15.6° . When two numbers are attached in the following table to the same salt, the second refers to a solution saturated at 100° and cooled to 15.6° .

Solubility and Specific Gravity at 15.6° .

Salt	Amount of Salt		Amount of water to 1 pt. of salt	Specific gravity	
	In 100 pts. of saturated solution	to 100 pts. of water		of the saturated solution	of the salt

Decomposition by Heat (Dissociation) of Salts in Solution. (C. R. C. Tiehborne, *Chem. News*, xxiv. 123, 199, 209, 230; xxv. 133.)—Experiments with solutions of ferric chloride, ferric sulphate, chromic sulphate, chrome-alum, ammonia-iron alum, potash-iron alum, ammonia alum, and potash alum (partly in sealed tubes at 177°), showed that all these compounds are more or less decomposed by heating their aqueous solutions, the ferric salts most easily of all. The solutions of these latter gradually become darker, and when dilute deposit, even below the boiling point, a pregradually become darker, and when dilute deposit, even below the boiling point, a precipitate of a basic salt; while at higher temperatures, under pressure, or in very dilute solutions even under ordinary circumstances, anhydrous ferric oxide may be formed. *Chromic salts* decompose in a similar manner, excepting that the point of decomposition is higher. In solutions of *aluminium salts* it is still considerably higher; these solutions give precipitates at the boiling heat under a pressure of 11 or 12 atmospheres, or even at 100° , if they contain from 50,000 to 60,000 pts. water to 1 pt. of salt.

Solubility of Mixed Salts at 15.6°, and Specific Gravity of the Solutions.

Solutions of *hydrated salts of cobalt, copper, and nickel* gave the following results:—Neutral aqueous solutions of the chlorides, *e.g.* the light rose-coloured solutions of cobalt chloride, do not change colour when boiled under ordinary atmospheric pressure. But in every case in which a difference of colour is observed between the dry and the hydrated salt, the dehydration may be brought about by increasing the pressure. Of the greatest importance is the observed opposite influence of dilution on salts which decompose, like ferric and chromic salts, with formation of a basic salt, and of those which merely suffer dehydration. In the former the temperature of decomposition is lowered by dilution, in the latter it is raised, as shown by the following table:

Decomposition of Ferric Chloride, with separation of base			Decomposition of Cobalt Chloride, with separation of hydration-water		
Percentage of Hydrated Salt in the solutions	Temperature of decomposition	Colour	Percentage of Hydrated Salt in the solutions	Temperature of decomposition	Colour

The decomposition by heat of certain ammonia salts and acetates in aqueous solution has been investigated by H. C. Dibbitts (*Deut. Chem. Ges. Ber.* v. 820). The ammonia salts named in the following table give off ammonia at ordinary temperatures, as well as at the boiling points of their solutions; a solution of the acetate, through which a stream of hydrogen was passed, gave off ammonia even at 0°. The quantity of free ammonia in the distillate is proportional to the concentration of the solution. The proportions of the several salts thus decomposed in solution are given in the following table:

Sodium acetate	0.14	p.c. at 100-102°	Ammonium chloride	0.062	p.c. at 100°
Barium "	0.064	" " 100-101.5	" nitrate	0.072	" "
Lead "	5.0	" " 100	" sulphate	1.1	" "
Silver "	0.72	" " 100	" oxalate	6.7	" "
			" acetate	7.9	" "

In the case of the chloride and acetate of ammonium, which give off acid as well as ammonia, these numbers must be regarded only as maxima.

For Favre a. Valson's experiments on the Dissociation of Crystallised Salts in Solution, see *CHEMICAL ACTION* (pp. 292-304).

For Berthelot's experiments on the state of Acid Salts in Solution, and on the Division of a base in Solution between two Acids, see pp. 286-290.

Supersaturated Saline Solutions.—These solutions are usually prepared by leaving a solution saturated while hot to cool in a vessel in which it is protected from the dust of the air. De Coppet (*Compt. rend.* lxxiii. 1324) finds that a supersaturated solution of sodium sulphate is formed when anhydrous sodium sulphate previously heated above 33° , and cooled out of contact with the dust of the air, is dissolved in cold water, the salt being added by small quantities at a time to prevent any considerable rise of temperature. By operating in this manner, water may be made to take up a quantity of sodium sulphate five times as great as that which is contained in a solution of the hydrate, $\text{Na}^2\text{SO}^4 \cdot 10\text{H}^2\text{O}$, saturated at the ordinary temperature.

In like manner supersaturated solutions of sodium carbonate and magnesium sulphate may be prepared without heating, by the use of anhydrous sodium carbonate and partially dehydrated magnesium sulphate.

On the causes which determine the separation of salts from supersaturated solutions, see Tomlinson (*Proc. Roy. Soc.* xvi. 493; xviii. 533, 536; xx. 41, 109, 342; *Phil. Mag.* [4], xxxvi. 222; xl. 221, 224, 295; xlv. 243; *Chem. Soc. J.* [2], vii. 125; x. 284, 784; xi. 720; *Jahresb. f. Chem.* 1868, 43; 1870, 44; 1871, 36; 1872, 20), Gernez (*Compt. rend.* lxxv. 1705; *Jahresb.* 1872, 20; *Chem. Soc. J.* [2], xi. 720), Van der Mensbrugghe (*Compt. rend.* lxxvi. 45; *Chem. Soc. J.* [2], xi. 721), Liversidge (*Chem. News*, xxii. 90; *Proc. Roy. Soc.* xx. 497; *Chem. Soc. J.* [2], xi. 469).

SALYLIC ACID. This name was given by Kolbe a. Lautemann to a supposed isomeric of benzoic acid, the existence of which has, however, not been satisfactorily established (v. 185).

The same name is applied by G. Städeler (*Ann. Ch. Pharm. Suppl.* vii. 159) to two acids, distinguished as α and β , derived from salicyl, $\text{C}^1\text{H}^2\text{O}^2$, by addition of the elements of water.

When salicyl which had stood for twelve years under water, was treated in the dry state with sodium-amalgam, the mass dissolved in water, the solution saturated with carbonic acid, the saligenin thereby produced dissolved out with ether, and the soda solution evaporated to dryness, the residue yielded to alcohol a sodium salt from which sulphuric acid separated an oily acid soluble in hot water and separating therefrom in small crystals. This acid, called by Städeler β -salylic acid, has the composition $\text{C}^{11}\text{H}^{10}\text{O}^4 = 3\text{C}^1\text{H}^2\text{O}^2 + 2\text{H}^2\text{O}$. It is sparingly soluble in cold water, easily soluble in alcohol and ether. It melts in the dry state at 94° - 95° , much more easily under water. A hot aqueous solution of the acid becomes turbid on cooling, from separation of oil-drops, which afterwards turn to crystals resembling benzoic acid, and giving off vapours of similar odour when heated. By slower crystallisation tufts of widely radiating crystals are obtained. The aqueous solution, even when very dilute, acquires a fine violet colour on addition of ferric chloride. The acid appears to be tribasic, but there appears to be considerable difficulty in obtaining its neutral salts.

Recently prepared salicyl similarly treated yielded only saligenin, without a trace of organic acid. This observation led to the suspicion that the β -salylic acid was contained in the salicyl, which had long been under water, and was not produced by the action of the sodium-amalgam; and this proved to be the case, for on dissolving the salicyl in soda, saturating with carbonic acid, agitating with ether, &c., two organic acids were obtained, separable by crystallisation. The one which separated first, called by Städeler α -salylic acid, had the composition $\text{C}^{11}\text{H}^{10}\text{O}^3 = 2\text{C}^1\text{H}^2\text{O}^2 + \text{H}^2\text{O}$; afterwards β -salylic acid crystallised out, but only in small quantity; so that it seems probable that α -salylic acid is resolved by the action of sodium-amalgam into water and β -salylic acid.

α -Salylic acid forms small, distorted, four-sided prisms with oblique end-face, sometimes shortened into rhombic or six-sided tables. It melts at 100° - 101° , dissolves easily in alcohol and ether, melts to an oil with water, and when heated alone gives off vapours which excite coughing. Its aqueous solution is not coloured by ferric chloride. It appears to be bibasic, but the neutral salts are difficult to obtain. The silver salt crystallises in small colourless needles, sparingly soluble in cold water, and containing 42.78 p.c. silver instead of 45.88, as required by calculation.

An attempt to prepare the two acids above described by heating salicyl with water did not yield definite results.

SARANGETH. See TANTALATES.

SARSUOLIN. $\text{C}^{10}\text{H}^{12}$. The terpene from elder oil.
2nd Sup. 3 Z

SANDAL or SANTAL WOOD OIL. By destroying the oxidised constituent of this oil with sodium, a small quantity of a hydrocarbon, $C^{12}H^{18}$, is separated, rather viscid, slightly soluble in alcohol, having a density of 0.9190, and a refractive index = 1.4867 for the line A. (Gladstone, *Chem. Soc. J.* [2], x. 6).

SANDBERGITE. From the analysis of this fahl-ore by Mehrbach (1st Suppl. 1012) Kenngott calculates that if Cu^2S be separated from RS , the mineral may be represented by the formula, $2(4Cu^2S.RS^2) + 4RS.RS^2$ (*Jahrbuch für Mineralogie*, 1871, 179).

SANTONIC ACID, $C^{13}H^{10}O^4$ (Cannizzaro a. Sestini, *Gazzetta chimica italiana*, iii. 241). This acid is formed by the prolonged action of hot alkaline solutions on santonin. 50 grams of crystallised santonin are gradually added, with agitation, to 500 grams of a boiling solution of barium hydrate, whereupon a white amorphous mass is deposited, consisting of the barium salt of santonin (*barium santonite* or *santoninate*). The liquid with the precipitate is boiled for about 12 hours in a flask, with reversed condenser, whereby the santonite is gradually converted into santonate, which dissolves, the liquid acquiring a yellow colour. Into this yellow solution, after cooling (and dilution with water, if barium hydrate has crystallised out), a stream of carbonic anhydride is passed as long as a precipitate is formed; the liquid is heated, filtered, and mixed with sulphuric acid, which precipitates barium sulphate, together with the greater part of the santonie acid; and the precipitate is collected on a filter, washed, dried, and treated with alcohol, which dissolves the santonie acid, together with a small quantity of yellow resinous matter. The alcoholic solution is evaporated, the residue treated with ether, and the resulting ethereal solution filtered and evaporated, whereupon it deposits santonie acid in fine large crystals, which have a faint yellowish colour, but may be obtained perfectly colourless by one or two fractional crystallisations from ether. For complete purification the product must be further crystallised by cooling from alcohol diluted with an equal bulk of water.

Santonie acid is colourless, and is not affected by the solar rays, which quickly turn santonin yellow. It is slightly soluble in cold water (100 pts. water at 17° dissolve 0.559 pt.); more soluble in hot water, from which it separates in prismatic crystals; very soluble in ether, still more in alcohol; moderately soluble also in chloroform and glacial acetic acid, very sparingly in carbon sulphide.

The crystals of santonie acid are orthorhombic, exhibiting the combination, $P\infty : P\infty : OP$, the macrodome generally predominating. Axes, $a:b:c = 0.4589:1:0.6544$; angle, $OP : P\infty = 114^\circ 39'$; $OP : P\infty = 123^\circ 12'$. Cleavage easy parallel to the faces $P\infty$.

Santonie acid melts at 161° – 163° (santonin at 170°), to a colourless liquid, which crystallises to a white mass on cooling, but often exhibits the phenomenon of superfusion. Fused santonie acid undergoes alteration at a temperature not exceeding 170° , turning brown, and giving off an odour like that of some of the pyrogenous products of santonin. With alcohol and caustic potash, it does not give the fine violet-red colour which is characteristic of santonin.

Santonates.—Santonie acid has a very decided acid reaction, and decomposes carbonates with brisk effervescence when the solution is heated with them. It is monobasic. The *sodium salt*, $C^{13}H^{10}NaO^4$, separates from a solution concentrated to a syrup and placed over sulphuric acid, as an amorphous, transparent, or vitreous mass, having a faint straw-yellow colour; but by open evaporation over the water-bath, it is obtained in radiate or stellar groups of needles. It is deliquescent, very soluble in water and in alcohol; soluble also in ether containing alcohol. The *silver salt*, $C^{13}H^8AgO^4$, obtained by precipitating the barium salt with silver nitrate, is white, but alters on exposure to light. It may be washed on a filter with cold water, in which, however, it dissolves somewhat freely. The *barium salt*, $(C^{13}H^8O^4)_2Ba$, is very soluble in water, but may be obtained in crystals by evaporating its concentrated solution over sulphuric acid. It is not precipitated from its aqueous solution by alcohol; but on adding a mixture of alcohol with a little ether to its concentrated aqueous solution, it separates in delicate needle-shaped crystals which remain for a long time suspended in the liquid.

H. Hvoslef (*Deut. Chem. Ges. Ber.* vi. 1471) states that he prepared santonie acid by the same process as Cannizzaro a. Sestini, as long ago as 1863. He gives the same formula and basicity for the acid, but finds that it melts at 171° .

The santonates of the heavy metals are, according to Hvoslef, for the most part soluble in boiling alcohol, and the solutions when cooled yield gelatinous masses which gradually crystallise.

The further action of baryta on the solution from which santonie acid has been precipitated by hydrochloric acid yields two bodies, one of which is apparently a sugar. Santonie acid would therefore seem to be a glucoside (Hvoslef).

SANTONIN, $C^{12}H^{10}O^2$. *Detection in Urine*.—W. G. Smith (*Pharm. J. Trans.* [3], i, 528), finds that the urine of a person who has taken santonin acquires a greenish-yellow colour, immediately changed to red by alkalis. The greenish-yellow colour, which sometimes approaches to a light saffron-yellow, is most easily observed by looking obliquely along the surface of the liquid. The reddening is produced by potash, soda, ammoniac, lime and baryta, but the reaction is most distinct with potash. With acids this urine gives reactions similar to those exhibited by urine containing bile. A small quantity of nitric acid produces in it a transient purple-red colour; sulphuric acid a red-brown colour, gradually changing to a darker brown. This reaction must be borne in mind in testing urine for bile. The reaction with alkali is so distinct, that santonin may with certainty be detected by it in the urine from 10 to 60 minutes after it has been swallowed. After a dose of 6 to 10 grains, the reaction was still perceptible after two days. The red liquid examined by the spectroscope showed that the red, orange and yellow rays were transmitted, whilst the blue end of the spectrum was absorbed. In very dilute solutions, the middle rays only were absorbed, the red and blue being transmitted.

The red colouring-matter may be isolated by lead acetate, and appears to be moderately permanent. It unites with basic lead acetate, and forms a brown precipitate with iron salts. It appeared, therefore, probable that the substance was a weak acid, formed by oxidation of santonin; and, indeed, by heating santonin with nitric acid, a greenish-yellow liquid is formed, which, when treated with an alkali, immediately acquires an orange-red colour, exactly like that which is produced by similar means in urine after ingestion of santonin. This colouring matter, however, is not identical with that separated from the urine, inasmuch as its solution is not precipitated by acetate of lead.

Santonites.—This name is applied by Cannizzaro & Sestini (*Gazzetta chimica italiana*, iii, 241) to the metallic derivatives of santonin, $C^{12}H^{10}RO^2$, originally called *santonates* by Heldt, who first examined them (v. 190). They are really salts of santoninic acid, and should therefore be called santoninates.

Cannizzaro & Sestini find that when sodium santonite, which, according to Heldt, contains four molecules of crystallisation-water, is heated above 100° , it is converted, by assimilation of the elements of one molecule of water, partly into santonate, partly into a substance having a red colour changing to brown.

Santonin Bromide, $C^{12}H^{10}O^2Br^2$, is formed on adding bromine to a solution of santonin in bromine, or in glacial acetic acid. It is best prepared by means of the latter solvent, the bromine being added in molecular proportion ($Br^2 : C^{12}H^{10}O^2 = 160 : 246$). After two or three hours the bromine-compound separates in fine, red, needle-shaped crystals, which must be collected on a well-dried double filter, washed four or five times with glacial acetic acid, pressed in the filter between two glass plates, then within several folds of thoroughly dried paper, placed between bricks and squeezed in a press, and finally dried over sulphuric acid or sticks of potash.

This compound dissolves with red colour in ether and in acetic acid; it emits a faint odour of bromine, absorbs water from the air, and quickly alters, yielding hydrogen bromide and a red-brown, amorphous substance. When heated in the water-bath, it first gives off bromine, then suddenly turns brown, and gives off large quantities of hydrogen bromide. In contact with water, it gives up its bromine in a few seconds, colouring the water yellowish-red. The solution is decolorised by potash, with formation of hydrobromic acid, and a white residue possessing all the properties of santonin.

From these reactions it may be inferred that the red compound is a brominated addition-product of santonin, although, on account of the difficulty of purifying it, the numbers obtained by analysis do not agree very closely with the formula, $C^{12}H^{10}Br^2O^2$ (35.24 and 35.42 p.c. bromine, instead of the calculated quantity of 39.41).

Action of Nascent Hydrogen on Santonin.—Santonin treated with water and sodium amalgam containing 3 p.c. sodium, gradually dissolves, forming a strongly alkaline liquid, which when treated, after cooling, with very dilute sulphuric acid, yields a white flocculent precipitate, which may be washed with cold water, dried by pressure between paper, and finally over sulphuric acid.

This white substance is soluble in ether, very soluble in alcohol, sparingly in water, and separates from these solvents in the amorphous state, with yellow colour and resinous aspect. Between 80° and 90° it becomes somewhat viscid; at 100° it turns yellow, and may be drawn out into threads, becoming hard and friable on cooling; between 107° and 109° it exhibits signs of actual fusion. Towards 120° it gives off slightly acid water, smelling like formic acid; towards 160° a few drops of an acid liquid which reduces silver nitrate; and above 180° a small quantity of oily matter, which solidifies to a white mass on cooling. When dissolved in glacial acetic acid and

treated with bromine, it gives off hydrobromic acid, even when the liquid is cooled, and does not yield any crystalline compound. This reaction indicates that it contains more hydrogen than santonin; that, in fact, it is a hydrosantonin; a view which accords with its mode of formation. It has not, however, been obtained in a state fit for analysis. It forms crystalline compounds with alkalis and alkaline earths (Cannizzaro a. Sestini, *loc. cit.*)

SANTONINIC ACID, $C^{12}H^8O^4$ (O. Hesse, *Deut. Chem. Ges. Ber.* vi. 1280). This acid, of which santonin is the anhydride, is isomeric with santonie acid. The so-called santonites are its salts, and it may be obtained in the free state by adding an excess of dilute hydrochloric acid to a cold aqueous solution of the sodium salt, and at once shaking the milky liquid with ether (at higher temperatures santonie acid is formed). From the ethereal solution granular crystals soon separate out, which may be recrystallised from alcohol.

Santoninic acid forms white, rhombic crystals, which are not coloured yellow by exposure to light. It is sparingly soluble in cold water, more freely in boiling water, and readily in alcohol, but not very freely in ether. Its aqueous solution has a strongly acid reaction, and when hot, decomposes the carbonates of sodium and calcium. The santoninates have an alkaline reaction, and are not coloured red by alcoholic potash. When the acid is heated to 120° , it is resolved into santonin and water; the same decomposition is produced by adding sulphuric acid to its aqueous solution; hydrochloric acts in the cold in a similar way, but more slowly, while by adding either of these acids to a hot solution of a salt, santonin is at once precipitated.

SANTONOL, $C^{12}H^{10}O^2$ (L. Saint-Martin, *Compt. rend.* lxxv. 1190). A monatomic phenol obtained from santonin. When one part of santonin and four parts of zinc are heated in a current of hydrogen, a brownish-yellow liquid is obtained, in which, after some days, needle-shaped crystals begin to form. These are purified by distillation at 350° , when two isomeric bodies neutral to litmus are obtained, the one crystalline and the other liquid, to both of which the name of *santonol* is given. Crystalline santonol is similar in appearance to stearin, and melts at 135° . It is insoluble in water, and very soluble in alcohol or ether. Sulphuric acid forms with it a sulpho-conjugated acid, the barium salt of which is soluble. Santonol dissolves when it is mixed with a moderate quantity of potash solution, but a large excess of potash gives rise to *potassium santonolate*, which is an oil yielding santonol on treatment with an acid.

Liquid santonol is very changeable on exposure to air. Like the solid, with which it is saturated, it is insoluble in water, but soluble in alcohol or ether.

SAPPANIN, $C^{12}H^{10}O^4$ (J. Schreder, *Deut. Chem. Ges. Ber.* v. 572). A crystallisable substance, obtained together with resorcin and a little pyrocatechin, by fusing the commercial extract of sapan wood with caustic soda. It is nearly insoluble in cold water, and separates readily from solution in hot water in crystals containing $C^{12}H^{10}O^4 \cdot 2H^2O$. By recrystallisation or by keeping in well-closed vessels, it acquires a faint red colour which is not removed by animal charcoal, but completely by zinc and sulphuric acid. Sappanin has no well-marked characteristics; it is neutral, soluble in alcohol, ether, and boiling water, and insoluble in chloroform, carbon sulphide, and benzene; it gives (in aqueous solution) a deep cherry-red colour with ferric chloride, and a dark grass green, soon becoming brown, with alkaline hypochlorites; bromine-water colours the liquid brown, and when added in excess causes resinous brown-black flakes to separate. Lead acetate gives a yellowish-white precipitate which becomes coloured and decomposed on drying. Ammoniacal silver-solution and Fehling's copper-solution are reduced on warming. Sappanin distils for the most part unaltered; nitric acid converts it into styphnic acid; melting caustic potash and nascent hydrogen produce no change.

Acetyl chloride acts readily on sappanin at ordinary temperatures, giving a product which is crystallisable from hot alcohol, and hardly soluble in water; this substance gives no colour with ferric chloride or hypochlorites, and appears to be tetracetylsappanin.

The production of styphnic acid shows that sappanin is a resorcin-derivative:—

It is perhaps related to resorcin in the same manner as diphenyl to benzene:

SARCINE, $C^8H^8N^2O$. This base is formed from carnine by the action of bromine-water (p. 270).

When sarcine is heated with fresh chlorine-water and a trace of nitric acid till the evolution of gas which takes place at first has slackened, and the liquid is then evaporated on the water-bath, a residuo is obtained which, when exposed under a bell-jar to an atmosphere containing ammonia, acquires a dark rose-red colour.

SARCOLACTIC ACID. See LACTIC ACID (p. 719).

SARCOSINE. *Reaction in the Animal Organism.*—When to a well-fed dog there was given, in addition to his ordinary food, a quantity of sarcosine containing nitrogen equal in amount to that which was daily excreted in the urine, the urea and uric acid disappeared completely from the urine, and instead of them, there were obtained: (1) splendid transparent, colourless, tabular crystals of a body having the composition $\text{H}^2\text{NCO}-\text{N}\begin{Bmatrix} \text{CH}^3 \\ \text{CH}^3\text{CO}^2\text{H} \end{Bmatrix}$; that is to say, urea having the two hydrogen-atoms attached to one of its nitrogen-atoms replaced by methyl and acetoxy, or sarcosine having a carbamic acid residue attached to its nitrogen; (2) An acid, $\text{H}^2\text{NSO}^2\text{N}\begin{Bmatrix} \text{CH}^3 \\ \text{CH}^3\text{CO}^2\text{H} \end{Bmatrix}$, formed by the combination of sulphamic acid and sarcosine, with elimination of water.

The formation of these substances may perhaps be explained as follows:—1. The sarcosine, in its passage through the animal organism, meets with the carbamic acid group, and unites therewith, with elimination of water, to form the substituted urea. If ammonia were to come in contact with this group, ordinary urea would be formed instead of sarcosine. 2. The sulphuretted acid above mentioned is formed by the union of the sarcosine with sulphuric acid. Under normal circumstances, the sulphamic acid pre-existing in the albumin yields sulphuric acid and ammonia, the latter of which unites with carbamic acid to form urea. Other bodies are formed at the same time (O. Schulzon, *Deut. Chem. Ges. Ber.* v. 578).

SCAPOLITE. A greenish-white translucent mineral from Attleborough, Bucks Co., Pennsylvania, has been recognised by Leeds (*Chem. News*, xxii. 73) as Scapolite (Nebergite). It occurs in granular limestone in imperfectly developed crystals, together with pyroxene, graphite, sphene, and phlogopite. Analysis gave:

SiO^2	AlO^2	FeO^2	MgO	CaO	Na^2O	K^2O	H^2O
47.47	27.61	trace	1.20	17.59	3.05	1.40	1.48 = 99.61.

SCHHEELITE. A monograph on the morphological and paragenetic relations of this mineral has been published by Max Bauer (*Pogg. Ann.* cxliii. 452; *abstr. Jahrb. f. Mineralogie*, 1871, 879; *Jahresb. f. Chem.* 1871, 1169).

The occurrence of scheelite at Domodossola in Piedmont is described by Le Nove Foster (*Jahrb. f. Mineralogie*, 1870, 233).

SCOLEZITE. Kenngott (*ibid.* 430) has examined the behaviour of Icelandic scolezite with acids. The powder, which has a very faint alkaline reaction, forms a jelly with hydrochloric, nitric, and sulphuric acids, and with the last-mentioned acid, macroscopic crystals of gypsum.

Igelström (*ibid.* 1869, 1223) found in scolezite occurring in white divergent needles in the diabase porphyry of Lundörsfjäll in Sweden:

SiO^2	AlO^2	CaO	H^2O
46.56	25.75	15.00	13.30 = 100.61.

SEA-WATER. On the estimation of Carbonic acid in sea-water, see p. 561.

On the detection of Gold in sea-water, see p. 574.

On the detection and estimation of Iodine in sea-water, see p. 670.

SEBIC or SEBACIC ACID. On the formation of Cetyl Alcohol by the distillation of this alcohol with caustic baryta, see p. 277.

SEDUM. The Biting Stonecrop (*Sedum acre*) has been examined chemically by E. Mylius (*Arch. Pharm.* [3], i. 97). The dried and powdered plant, treated successively with ether, alcohol, cold, hot, and acidulated water, yielded—besides wax, chlorophyll, and other vegetable matters—rutin, and a small quantity of a peculiar alkaloid, amorphous, and forming very soluble salts. The rutin, by boiling with dilute acid, yielded quercetin and a sugar which reduced an alkaline cupric solution.

Sedum calcarum contains, according to Baudrimont (*Compt. rend.* lxxiv. 877), 87.81 p.c. water and volatile matter, 7.76 organic matter, and 3.11 mineral matter.

SEEBACHITE. This name is given by Max Bauer (*Jahrb. f. Mineralogie*, 1872, 739) to a mineral from Richmond in Victoria, formerly regarded as Herschelite (*Jahresb. f. Chem.* 1870, 1301; 1871, 1159). It agrees with Herschelite in crystalline form, but differs from it considerably in chemical composition (iii. 150).

An analysis by Kerl gave the values A, which Bauer refers to the formula $\{2(\text{Na}^+\text{O} \cdot 2\text{Al}^+\text{O}^{\cdot} \cdot 7\text{SiO}^{\cdot} + 12\text{H}^+\text{O})\}$, requiring the values B.

	SiO^{\cdot}	$\text{Al}^+\text{O}^{\cdot}$	CaO	Na^+O	K^+O	H^+O	
A. . .	43.7	21.8	8.5	3.5	trace	22.2	= 99.7
B. . .	43.6	21.6	8.5	3.7	—	22.6	= 100

Konngott designates the same mineral as Levyn.

SEEDS. On the effect of various substances in promoting or retarding the Germination of seeds, see A. Vogel (*N. Rep. Pharm.* xx. 132; *Chem. Soc. J.* [2], ix. 748). On the influence of Germination on the amount of Fat in seeds, see A. Müntz (*Ann. Chim. Phys.* xxii. 472; *Chem. Soc. J.* [2], ix. 1207); also A. Vogel (*N. Rep. Pharm.* xx. 693; *Chem. Soc. J.* [2], x. 317).

On the percentage of Fat in Oil-seeds, see p. 506 of this volume.

Apparatus for the Extraction of Oil from seeds: see H. Vohl (*Dingl. pol. J.* cci. 171).

SELAGITE. A dark-coloured micaceous volcanic rock from Monte Catini. It occurs imbedded in mica, has a specific gravity of 2.789, hardness 4.5, and contains:

SiO^{\cdot}	$\text{Al}^+\text{O}^{\cdot}$	FeO	MgO	CaO	Na^+O	K^+O	$\text{P}^+\text{O}^{\cdot}$
44.5	1.7	37.3	1.4	14.0	trace		1.1 = 100

(E. Bechi, *Sill. Am. J.* [4], xlix. 401).

SELENIOTRITHIONIC ACID, $\text{H}^+\text{SeS}^2\text{O}^{\cdot}$. See TRITHIONIC ACID, under SULPHUR.

SELENITE. On the crystalline form of this mineral, see F. Schrauf (*Jahrb. f. Mineralogie*, 1871, 881).

SELENIOWALERALDEHYDE, $\text{C}^{\cdot}\text{H}^+\text{Se}$. See VALERALDEHYDE.

SELENIUM. *Occurrence.*—Ch. Violette (*Compt. rend.* lxx. 729) has found selenium in copper, probably from Chilo. To detect the selenium the copper was oxidised in a muffle, and the oxide, heated to redness in a tube, was subjected for several hours to a stream of pure dry air. The selenium was then deposited on the colder part of the tube in the form of a white ring of selenious oxide.

The occurrence of selenium in sulphuric acid prepared from seleniferous pyrites is described by J. Personne (*ibid.* lxxiv. 1109), Lamy (*ibid.* 1285), and Scheurer-Kestner (*ibid.* 1286); see also *Chem. Soc. J.* [2], x. 595.

On the Refraction and Dispersion of selenium, see LIGHT (p. 741).

Absorption-spectrum.—When selenium is heated in a porcelain tube by a series of gas jets, whilst a ray of white light is passed through the tube, the spectrum is found to be gradually extinguished from the violet up to the red, without any appearance of black lines; on raising the temperature considerably, the spectrum becomes brighter, and bundles of black lines appear, furrowing the blue and violet. This spectrum resembles that of selenious anhydride, but as it was obtained in an atmosphere of dry carbonic anhydride, the formation of selenious anhydride is impossible.

Vapour of selenious chloride gives an absorption-spectrum of lines which extend from the green to the violet.

Vapour of selenious bromide produces a system of lines almost equidistant when observed in a thickness of 10 centimeters (Gernez, *Compt. rend.* lxx. 1100).

On the spectrum of selenium, see further, SALT (*Compt. rend.* lxxiii. 1145; *Chem. Soc. J.* [2], ix. 1145), and Ditto (*Compt. rend.* lxxiii. 622; *Chem. Soc. J.* [2], ix. 1146).

Action of Light on the Electric Resistance of Selenium.—The electric conductivity of crystalline selenium varies with the degree of light to which it is exposed. A bar of selenium having been enclosed in a box and the resistance measured in the usual manner, on opening the box suddenly, and exposing the selenium to daylight, the resistance fell instantaneously and considerably; on exposing it in like manner to full sunshine, the resistance was so greatly diminished that it was less by one-half than the measurement taken in darkness.

The bar was also exposed to the rays of the solar spectrum successively. The least resistance was observed in the extreme red rays, and the greatest in the violet and blue rays; it will be noticed, therefore, that the locus of the maximum heat-rays is nearly coincident with the point of minimum resistance.

The spectrum of the electric light produced a very feeble effect, but the phenomena were identical with those produced by the solar spectrum.

This variation in the electric resistance of selenium is not due to any change in the temperature of the bar (Lieut. Sale, R.E., *Proc. Roy. Soc.* xli. 233).

On the Heat of Combination of Selenium with Oxygen and Hydrogen, see *Heat* (pp. 613, 615).

On the Heat of Neutralisation of Selenious and Selenic acids, see *1st Suppl.* 1086.

Chlorides (Michaelis, *Jenaische Zeitschr.* vi. 86). When selenious anhydride is placed in contact with phosphorus pentachloride, great heat is evolved, and the mass gradually liquefies; but if further heated it again becomes solid. The first reaction is analogous to that of the pentachloride on sulphurous anhydride, the products being selenium oxychloride or selenyl chloride, and phosphoryl chloride:

and the phosphoryl chloride then acts further on the selenyl chloride, forming phosphoric anhydride and selenium tetrachloride:

This last reaction is in fact produced when selenyl chloride is directly heated with phosphoryl chloride. The action of phosphorus pentachloride on selenious anhydride affords a quick and easy method of preparing the tetrachloride of selenium.

Selenyl chloride boils at 179.5° (corr.), not at 220° , as stated by Weber (v. 233), and solidifies below 0° to a colourless crystalline mass, which begins to melt at 10° . Sp. gr. = 2.443 at 13° .

Ammonia acts on selenyl chloride according to the equation:

When phosphorus trichloride is added by drops to selenyl chloride in a cooled vessel, selenium tetrachloride crystallises out, and diselenium dichloride is formed at the same time, the liquid turning red:

Hydride. *Hydrogen Selenide.* *Selenhydric acid*, H_2Se . *Formation and decomposition.*—Hautefeuille showed (*Compt. rend.* lxiv. 608) that selenium and hydrogen unite directly at about 440° . According to A. Ditte (*ibid.* lxxiv. 980) the quantity of hydrogen selenide thus formed is a function of the temperature. It increases from 250° to 520° , and decreases regularly from the latter point to 700° . If the application of heat be limited to the part of the tube containing the selenium, as much hydrogen selenide is formed as when the whole of the tube is heated; but selenium is deposited on the colder part in beautiful shining crystals, which continue to increase as long as there is any selenium remaining in the heated part of the tube. This apparent volatilisation of the selenium is due, in fact, to decomposition of hydrogen selenide previously formed. The quantity of the gas thus decomposed is greater as the temperature to which the cooler part of the tube has fallen is nearer to 270° . The decomposition of hydrogen selenide begins, though very slowly, at 150° , is considerable at 270° , and diminishes slowly above that temperature, attaining a minimum at 520° , and increases again at higher temperatures. That the deposition of the crystallised selenium in the experiment above described is really due to decomposition of hydrogen selenide, and not to simple volatilisation of the selenium, is proved by substituting for the hydrogen a gas which does not act on selenium; in this case the upper part of the tube merely becomes coated with a red opaque film.

Oxides and Oxygen Acids. *Selenious Anhydride*, SeO_2 .—When this compound is brought in contact with phosphorus trichloride, both bodies become hot and red, but undergo no further alteration in the cold. Heated together in a sealed tube to 100° and afterwards to 110° , they yield phosphoryl chloride and free selenium:

In one experiment, in which the temperature was raised to 130° , the phosphoryl chloride acted on the still unreduced selenious oxide, in such a manner as to produce selenium tetrachloride, which was then reduced by the free selenium to diselenium dichloride (Michaelis, *Jenaische Zeitschrift*, vi. 93).

Selenates.—*Ammonium Selenate*, $(\text{NH}_4)_2\text{SeO}_4$, forms monoclinic crystals having the axes $a : b : c = 1.2065 : 1 : 1.908$, and angle $b o = 64.27^\circ$. The observed forms (expressed in Miller's notation) are 001, 100, 102, 011, 111, 111. The salt has the same composition as the rhombic ammonium selenate, isomorphous with the sulphate, described by v. Lang (*Wien. Akad. Ber.* [2. Abth.], xlv. 109), with which, however, it has no crystallographic relation (Topsoe, *ibid.* lxxvi. 5).

Glucinum Selenate, $\text{GSeO}_4 + 4\text{H}_2\text{O}$, crystallises in the rhombic system; $a : b : c = 0.9802 : 1 : 0.90275$. Observed forms, 011, 101, 021, 111, 001. It is

analogous in composition to the sulphate $\text{GSO}^4 + 4\text{H}^2\text{O}$, which crystallises in the quadratic system, and when mixed solutions of these two salts are left to evaporate slowly, mixed crystals are obtained, quadratic if 7.33 or more atoms of sulphuric acid are present to 1 at. selenic acid, rhombic in the contrary case (Topsoë, *loc. cit.*)

Sulphides. (Bettendorff a. vom Rath, *Pogg. Ann.* cxxxix. 329.) When selenium and sulphur are fused together in the most various proportions, the fused mass left to solidify partially, and the remaining liquid portion poured off, no crystalline products are obtained, the fused masses remaining pasty and completely destitute of crystalline structure. By solution in carbon sulphide, however, in which they gradually dissolve, they may be slowly brought into the crystalline state. This metamorphosis takes place in a short time at 100° , and more quickly as the proportion of sulphur in the compound is larger.

The following products were obtained by fusing 1 at. selenium with 2, 3, and 4 at. sulphur, heating the mixture for some time to 100° , dissolving it in carbon sulphide, and evaporating the solutions. The masses which contained 1 at. selenium to 2 and 3 at. sulphur yielded in this manner monoclinic crystals from 2 to 4 mm. long, which were previously observed by Rathke, but described by him as rhombic (1st *Suppl.* 1015). At first there separated deep red crystals rich in selenium; afterwards light orange-coloured crystals containing but a small proportion of that element; and between these occurred crystallisations varying in colour as well as in composition.

The solution of the fused mass obtained with 4 at. sulphur to 1 at. selenium deposited, on evaporation, first small monoclinic crystals of the colour of chromic acid, then others having the colour of acid potassium chromate, and finally a mixture of lighter-coloured crystals with numerous large orange-red rhombic octohedrons, agreeing nearly in composition with the formula SeS^4 .

The products which approximated in composition to the formulæ SeS^3 and SeS^4 yielded, when their solutions were left to evaporate, first deposits comparatively rich in selenium, afterwards deposits containing more sulphur, and could not therefore be recrystallised without decomposition. The same is the case with the rhombic octohedrons. On dissolving them in carbon sulphide they become opaque, indicating that they pass into a different modification in dissolving. The solution first deposits prismatic crystals comparatively rich in selenium, then follow the orange-red rhombic crystals of various shades of colour, and lastly pure sulphur separates.

With exception of the rhombic octohedrons just mentioned, all the crystals examined by Bettendorff and vom Rath, and obtained from mixtures of sulphur and selenium in the proportions, $\text{Se} : \text{S}^3$, $\text{Se} : \text{S}^4$, $\text{Se} : \text{S}^5$, have the same form and belong to the monoclinic system, with the following axial ratios:

Clinoïdagonal	Orthoïdagonal	Principal axis
1.0546	1	0.7146

Angle of inclined axes $= 91^\circ 43' 35''$. Combination $\infty\text{P}2. (\infty\text{P}\infty) - \text{P.P.} (\frac{1}{2}\text{P}\infty)$. Angle $\infty\text{P}2 : \infty\text{P}2 = 124^\circ 22'$; $-\text{P} : -\text{P} = 119^\circ 30'$; $-\text{P} : \infty\text{P}2 = 132^\circ 35'$. They also form twins (like those of gypsum) with the twin-plane $-\text{P}\infty$, which does not occur as a crystal-face. The rhombic octohedrons, which have nearly the composition SeS^3 , exhibit the form and angles of rhombic sulphur.

Ditte (*Compt. rend.* lxxiii. 625, 660) has obtained a crystallised selenium sulphide, SeS , by saturating a very dilute solution of selenious acid, cooled to a temperature between 5° and 0° , with hydrogen sulphide previously passed through a bottle filled with ice. The compound then separates as a fine lemon-yellow powder, which, after being well washed and dried in a vacuum, may be brought into the crystalline state by moistening it with a small quantity of carbon sulphide. Crystallisation then begins on the surface, and in a few days the entire precipitate is converted into crystals, while the carbon sulphide becomes saturated with sulphur. This saturated liquid is decanted and replaced by fresh carbon sulphide, the latter poured off after a few seconds, and the product washed, first with pure benzene, then with alcohol. Its formation is represented by the equation:

Selenium sulphide thus prepared forms small, shining, transparent, orange-yellow laminae, of sp. gr. 5.056 at 0° , 3.035 at 52° . The expansion-coefficient between these limits is 0.00014176; the specific heat 0.1274. When heated it melts, and gives off first sulphur-vapour, then mixed vapours of sulphur and selenium. It is insoluble in water and in ether, but dissolves in carbon sulphide. In contact with absolute alcohol it blackens, and is gradually resolved into its constituents.

SENNA. See CATHARTIN (p. 270); also *Chem. Soc. J.* [2], ix. 1068.

SERICIC ACID. An acid prepared from silk in the same manner as leucogenic acid from wool (p. 724). By evaporation of its aqueous solution it is obtained as a

yellowish, translucent, uncrystallisable, deliquescent mass, soluble in ether and in alcohol. From the analysis of its barium salt it appears to have the composition $C^{10}H^{10}NO^{14}$ (P. Champion, *Compt. rend.* lxxii. 330).

SERICITE. This mineral, from the Taunus range in Western Germany, regarded by List as identical with damourite (v. 235), is, according to v. Lasaulx (*Jahrb. f. Mineralogie*, 1872, 851), a mixture of several compounds.

SERPENTINE. S. Meunier (*Compt. rend.* lxxiv. 1325) has examined a number of grey serpentines from the Alps, Brazil, the Grecian Archipelago, &c., and finds them to be composed of magnetic iron ore, augite, olivin, and a hydrated silicate of magnesium. The entire analysis of a specimen from which the several varieties examined did not differ materially, yielded the following numbers:

SiO ²	Al ² O ³	MgO	CaO	FeO	H ² O	Sp. gr.
39.90	1.25	38.10	2.00	6.42	11.60 = 90.27	2.37-2.52

Proximate analysis yielded 0.79 p.c. magnetic iron ore and 0.80 undecomposable silicate (augite); the rest was decomposable, and could be separated by treatment with alkalis into an anhydrous mineral (olivine) and a hydrated mineral. These results were confirmed by microscopic examination.

Respecting Meunier's views of the relation of serpentine to meteorites, see p. 793.

A serpentine from the Timbertop mountain, Victoria, Australia, analysed by C. Newbery (*Jahrb. f. Mineralogie*, 1871, 464), gave:

SiO ²	Al ² O ³	Fe ² O ³	MgO	H ² O
39.9	8.2		36.8	15.4 = 100.3.

Rocks allied to the serpentine group, from North Tyrol and Carinthia, have been analysed by R. v. Drosche (*ibid.* 1871, 322; *Jahresb. f. Chem.* 1871, 1205).

SILICA. SiO². *Separation from Aqueous Solutions.*—When a solution of sodium silicate is strongly heated in sealed glass tubes, the glass is attacked layer by layer, and silica is dissolved, forming a more acid sodium silicate, which, on cooling, deposits free silica in nodules. The glass, by losing silica, is converted layer by layer into a more basic silicate, which, by taking up water, is ultimately transformed into a stratified zeolitic substance. At about 180° and above, free silica separates from aqueous alkaline solutions in the form of quartz; below 180° in that of tridymite; at still lower temperatures as crystallised, and finally as amorphous hydrate of silica. At ordinary or slightly higher temperatures, and under ordinary pressure, quartz is not formed under any circumstances (O. Maschke, *Pogg. Ann.* cxlv. 549; cxlvi. 90).

According to Rammelsberg (*Deut. Chem. Ges. Ber.* v. 1006), silica, as it is obtained in the analysis of silicates, is, after prolonged ignition, insoluble in a concentrated solution of potassium or sodium carbonate. This ignited silica has a specific gravity of 2.3, and must therefore have passed into the crystallised state of tridymite.

Hydrates. Silica, separated from alkali-silicates (or from Wollastonite), contains, after drying over sulphuric acid, from 4.5 to 4.7 p.c. water; after drying at 100°-140°, it contains 4 to 5.7 p.c. water. These numbers represent hydrates $nSiO^2 + aq$, in which n lies between 4 and 8. Air-dried silica does not contain any constant amount of water. Dry dusty silica contains from 36 to 13 p.c. water, or has a composition between $SiO^2 + 2aq$, and $2SiO^2 + aq$. Between these limits quantities equal to 23 and 15 p.c. water are the most frequent, or hydrates containing $SiO^2 + aq$, and $3SiO^2 + 2aq$ (Rammelsberg).

J. Gottlieb (*J. pr. Chem.* [2], vi. 185) finds that pure silica (prepared from silicofluoric acid), dried at 100° in air freed from moisture by standing over oil of vitriol, contains 4.47 p.c. water, which is nearly the same as that contained in silica dried in ordinary air at 130°-140°. Between 180° and 200°, the quantity diminishes to 4.18 p.c.

Solubility in Ammonia.—Pribram (*Zeitschr. anal. Chem.* vi. 119) found that silica in all its states is more or less soluble in aqueous ammonia (1st *Suppl.* 1017). These observations have been confirmed by Souchay (*Zeitschr. anal. Chem.* 1872, 182). Gelatinous silica, in the very loose state in which it is obtained by mixing a dilute solution of water-glass with hydrochloric acid to acid reaction, and then washing it and thoroughly, dissolves at first very easily in aqueous ammonia (of 0.96 sp. gr., and 9.75 p.c. NH^3); on continually adding silica, the liquid becomes turbid, and at last attains a state intermediate between solution and suspension. After filtration, it was found to contain in one experiment 1 gram of silica to 86.5 pts. of aqueous ammonia, in another 1 to 156. Pribram found 140. Silica prepared as above, and dried at 100°, till its weight became constant, required for solution from 252 to 271, mean 261.6 pts.,

aqueous ammonia to 1 pt. silica. One part of ignited silica dissolved in 280 pts.; 1 pt. silica in the form of rock-crystal, in 12097 pts. aqueous ammonia.

On the action of silica on sodium carbonate at high temperatures, see Maillard (*Compt. rend.* lxxv. 472; *Chem. Soc. J.* [2], xi. 243; *Jahresb. f. Chem.* 1872, 230).

SILICATES. To estimate the alkalis in a silicate, J. Lawrence Smith decomposes it by ignition with pure calcium carbonate and sal-ammoniac. For the details of the process, see *Ann. Ch. Pharm.* cliv. 82; *Sill. Am. J.* [3], i. 269; *Chem. News*, xxiii. 222, 234; *Jahresb.* 1871, 914.

SILICIC ETHERS. A. Ladenburg (*Ann. Ch. Pharm.* clxiv. 300) has published an elaborate research on the reduction-products of silicic ether, $\text{Si}(\text{OC}^2\text{H}^5)^4$, and their derivatives. By the joint action of *zinc-ethyl* and *sodium* on this ether, the following products are obtained:

		Boiling point
Orthosilicopropionic ether	$\text{Si}(\text{C}^2\text{H}^5)(\text{OC}^2\text{H}^5)^3$	168.5°
Silicodiethyl ether	$\text{Si}(\text{C}^2\text{H}^5)^2(\text{OC}^2\text{H}^5)^2$	169°
Silicotriethyl or Silico- heptylic ether	$\text{Si}(\text{C}^2\text{H}^5)^3(\text{OC}^2\text{H}^5)$	155.5°
Silicon-ethyl	$\text{Si}(\text{C}^2\text{H}^5)^4$	163°
Silicoheptylic hydride	$\text{Si}(\text{C}^2\text{H}^5)^3\text{H}$	107°

1. *Orthosilicopropionic Ether*, $\text{Si}(\text{C}^2\text{H}^5)(\text{OC}^2\text{H}^5)^3$, is produced in this manner much more readily than by the process originally described, viz., treatment of the chloride, $\text{SiCl}(\text{OC}^2\text{H}^5)^3$, with zinc-ethyl and sodium (1st *Suppl.* 1020). When warmed with hydriodic acid of boiling point 127° it decomposes, producing silicopropionic acid, $\text{Si}(\text{C}^2\text{H}^5)(\text{OC}^2\text{H}^5)^3$, in accordance with the equation:

this is, in fact, the most convenient way of preparing silicopropionic acid.

Heated with *benzoyl chloride*, orthosilicopropionic ether undergoes the reaction:

ethyl benzoate and silicopropionic trichloride (silicon-ethyl trichloride) being produced. This latter has not been obtained perfectly pure; it boils at about 100°, and is decomposed by moist air; water or aqueous ammonia produces hydrogen chloride and silicopropionic acid.

Phosphorus pentachloride appears to act on orthosilicopropionic ether, in accordance with the equation:

a remarkable action, inasmuch as bodies containing OC^2H^5 , associated with carbon, are for the most part not attacked by phosphorus pentachloride (Henry, *Deut. Chem. Ges. Ber.* 1869, 664).

The compound, $\text{Si}(\text{C}^2\text{H}^5)(\text{OC}^2\text{H}^5)^2\text{Cl}$, passed over between 148° and 163°, but could not be freed from phosphorus oxychloride, even by repeated fractional distillation.

2. *Silicodiethyl Ether*, $\text{Si}(\text{C}^2\text{H}^5)^2(\text{OC}^2\text{H}^5)^2$, boils at 165.8°, has the specific gravity 0.8752 at 0°, and the vapour-density 173.9 (calculated 176); it is stable in the air, insoluble in water, soluble in alcohol and in ether; unlike orthosilicopropionic ether, it does not yield silicopropionic acid by the action of concentrated sulphuric acid, and is not attacked by alcoholic ammonia; it is acted on by concentrated potash-ley only after several hours' heating, the reaction being probably

When silicodiethyl ether and *acetyl* or *benzoyl chloride* are heated together to 200° in a sealed tube in the proportions denoted by the following formulae (the former slightly preponderating) a reaction takes place represented by the equation:

silicodiethyl chloroethylin being formed, which boils between 146° and 148°, and is changed by contact with water into a viscid oil free from chlorine. If, however, two molecules of acetyl or benzoyl chloride and one of silicodiethyl ether are heated to 260°, silicodiethyl chloride, $\text{Si}(\text{C}^2\text{H}^5)^2\text{Cl}^2$, is produced, boiling between 128° and 130°:

The vapour of this body mixed with air is explosive. Water decomposes it, forming hydrogen chloride, and a syrupy substance which contains no chlorine; this is silicodiethyl oxide, $\text{Si}(\text{C}^2\text{H}^5)^2\text{O}$; it may be more conveniently prepared by the

action of aqueous hydriodic acid (boiling at 127°) upon silicodiethyl ether, according to the equation:

It is a thick syrup, distilling unchanged above the boiling point of mercury, not solidifying at -15° ; it is insoluble in water, difficultly soluble in alcohol, and readily soluble in ether.

From its formula and origin this body appears to be diethyl ketone, $\text{CO}(\text{C}^2\text{H}^5)^2$, having its carbon replaced by silicon; unlike carbon ketones, however, it does not combine with unscent hydrogen to form a secondary alcohol; moreover it yields silicopropionic acid on boiling for a day with concentrated soda-ley, whereas diethyl ketone yields only acetic acid by oxidation (Chapman a. Smith). It forms a notable exception to Mendelejoff's rule that silicon-compounds boil at a lower temperature than the corresponding carbon-compounds, as do also the following bodies:—

	Boiling point		Boiling point
$\text{Si}(\text{OC}^2\text{H}^5)^4$	166.5°	$\text{C}(\text{OC}^2\text{H}^5)^4$	128°
$\text{Si}(\text{C}^2\text{H}^5)^3\text{OH}$	154.0°	$\text{C}(\text{C}^2\text{H}^5)^3\text{OH}$	141°
$\text{Si}(\text{C}^2\text{H}^5)^3\text{H}$	107°	$\text{C}(\text{C}^2\text{H}^5)^3\text{H}$	96°
$\text{Si}(\text{CH}^3)^4$	30°	$\text{C}(\text{CH}^3)^4$	9°

3. *Silicotriethyl Ether* or *Silicoheptylic Ether*, $\text{Si}(\text{C}^2\text{H}^5)^3(\text{OC}^2\text{H}^5)$, boils at 163° , and has the specific gravity 0.8393 to 0.8414 at 0° , and the vapour-density 161.6° (calculated 160°); it is stable in the air, soluble in ether and alcohol, and insoluble in water. It is not attacked by alcoholic ammonia, or by aniline at 250° , but is decomposed by water at that temperature; it is soluble in concentrated sulphuric acid, wherein it differs from silicon-ethyl.

Acetyl chloride acts on silicotriethyl ether at 180° , producing silicoheptyl chloride or silicotriethyl chloride, $\text{Si}(\text{C}^2\text{H}^5)^3\text{Cl}$; thus:

Silicoheptyl chloride is a colourless liquid, which fumes in the air, and burns with a green-edged flame, leaving a white residue. It has a pungent camphorous odour, boils at 143.5° , and has a specific gravity of 0.9249 at 0° . It is slowly decomposed by water; absolute alcohol appears not to act upon it in the cold, whereas silver nitrate immediately decomposes it with separation of silver chloride. It does not act on mercuric cyanide even at 270° , neither can its chlorine be replaced by hydrogen (by treatment with sodium-amalgam and glacial acetic acid).

With aniline, silicoheptyl chloride yields aniline hydrochloride. On dropping it into aqueous ammonia, triethyl-silicol, silicoheptyl alcohol, or silicoheptyl hydroxide, $\text{Si}(\text{C}^2\text{H}^5)^3\text{OH}$, separates out nearly pure, provided that the liquid has not been allowed to become hot and acid; in the contrary case silicoheptyl oxide or silicotriethyl oxide, $\text{Si}^2(\text{C}^2\text{H}^5)^4\text{O}$, is produced:

Triethyl-silicol is more easily produced by heating silicoheptyl ether with acetic anhydride to 250° , whereby silicoheptyl-acetic ether, $\text{Si}^2(\text{C}^2\text{H}^5)^4\text{O.C}^2\text{H}^3\text{O}$, is formed, and decomposing this compound with a dilute solution of sodium carbonate:

Triethyl-silicol is a colourless viscid liquid, having a strong camphor-like odour, burning with a bright flame, and leaving a residue of silica. It is insoluble in water, slightly soluble in aqueous sodium carbonate, and miscible with alcohol and ether. Boiling point, 164° . Sp. gr. = 0.8700 at 0° . Determinations of the vapour-density gave for the molecular weight the numbers 134.8 and 124.3 (calc. 132).

Triethyl-silicol exhibits alcoholic characters, as shown by the following reactions:

A. With acetyl chloride it yields silicoheptyl acetate; thus:

the product being, however, decomposed by the hydrochloric acid as fast as formed:—

B. Sodium evolves hydrogen, giving sodium silicolate, $\text{Si}(\text{C}^2\text{H}^5)^3\text{ONa}$.

C. An ethereal solution of this latter yields, on passing carbon dioxide into it, an amorphous body, which is silicoheptyl-sodium carbonate, $\text{Si}(\text{C}^2\text{H}^5)^3\text{O.CO.ONa}$. When heated to redness, this body decomposes, leaving sodium carbonate; thus:

D. *Hydriodic acid*, boiling at 127°, acts on triethyl-silicol at 200°, forming ethane and silicodiethyl oxide:

E. *Oxidising agents*, such as *chromic* and *permanganic acids*, have no action on triethyl-silicol; Nordhausen sulphuric acid, however, converts it into silicopropionic acid, $\text{Si}(\text{C}^2\text{H}^5)_2\text{O}^2\text{H}$, according to the equation:

the reaction being analogous to that which tertiary alcohols undergo by oxidation (Butlerow, *Deut. Chem. Ges. Ber.* 1871, 931).

F. *Dehydrating agents*, such as *phosphoric anhydride*, convert triethyl-silicol into its corresponding ether, silicoheptyl oxide, $\{\text{Si}(\text{C}^2\text{H}^5)_2\}_2\text{O}$.

Silicoheptyl oxide may also be obtained by the action of hydriodic or sulphuric acid on silicoheptyl-ethyl ether, or by that of potash-ley on silicotriethyl chloride or bromide. It is a colourless, syrupy liquid, boiling at 231°, and of sp. gr. 0.850 at 0°; it is soluble in sulphuric acid, and separates therefrom unchanged on dilution, if heating is avoided; otherwise some triethyl-silicol is formed.

4. *Silicoheptyl hydride*, $\text{Si}(\text{C}^2\text{H}^5)_3\text{H}$, is the last product of the action of sodium and zinc-ethyl on silicic ether; it boils at 107°, and resembles the petroleum hydrocarbons in smell; it is insoluble in water and in concentrated sulphuric acid, soluble in ether and alcohol. It is stable in the air, and burns with a brilliant flame, leaving silica; its specific gravity at 0° is 0.751, and its vapour-density 118.4 (calculated 116). Nitric acid and Nordhausen sulphuric acid attack it readily, the latter producing the reaction:

Bromine added drop by drop to the well-cooled liquid, gives hydrogen bromide and silicoheptyl bromide, $\text{Si}(\text{C}^2\text{H}^5)_3\text{Br}$, boiling at 161°, and forming silicotriethyl oxide by the action of caustic alkalis; also triethyl-silicol with ammonia.

5. Simultaneously with silicoheptyl hydride, silicon-ethyl, $\text{Si}(\text{C}^2\text{H}^5)_4$, is formed by the action of zinc-ethyl and sodium on silicic ether; the body obtained boiled at 151°–153°, and had the properties of the silicon-ethyl of Friedel and Crafts (v. 266).

A small quantity of high-boiling silico-carbonaceous substances was also formed, probably reduction-products of polysilicic ethers.

The specific gravity of the bodies belonging to the silicon-ethyl-oxethyl series diminishes with the diminution in oxygen, but not regularly:

$\text{Si}(\text{C}^2\text{H}^5)_3\text{O}^1$	0.9676
$\text{Si}(\text{C}^2\text{H}^5)_2\text{O}^2$	0.9207
$\text{Si}(\text{C}^2\text{H}^5)_2\text{O}^3$	0.8752
$\text{Si}(\text{C}^2\text{H}^5)_2\text{O}^4$	0.8403
$\text{Si}(\text{C}^2\text{H}^5)_2\text{O}^5$	0.8341

The substitution of C^2H^5 for Cl raises the boiling point:

SiCl^4	.	.	58°	$\text{SiCl}^3\text{C}^2\text{H}^5\text{O}$.	104°	$\text{SiCl}^2(\text{C}^2\text{H}^5)_2\text{O}^2$.	137°
$\text{SiCl}^3\text{C}^2\text{H}^5$.	.	100	$\text{SiCl}^2(\text{C}^2\text{H}^5)_2\text{O}$.	?	$\text{SiCl}(\text{C}^2\text{H}^5)_3\text{O}^3$.	151

SILICO-ACETIC ANHYDRIDE, $\text{Si}(\text{OC}^2\text{H}^3\text{O})^4$ (Friedel a. Ladenburg, *Ann. Chem. Phys.* [4], xxvii. 428). This compound is obtained by digesting silicon tetrachloride with a mixture of acetic acid and acetic anhydride, and is deposited, on cooling, in beautifully white crystals, apparently belonging to the quadratic system.

Silico-acetic anhydride, when dropped into water, is decomposed with a hissing noise, gelatinous silica and acetic acid being formed. It cannot be distilled under the ordinary pressure, as it is decomposed at a temperature of 160°–170° into silica and acetic anhydride; but if the pressure be reduced to 5 or 6 millimeters, it passes over unchanged at about 148°, and condenses in beautiful white crystalline masses, melting at about 110°. It is decomposed by alcohol, with formation of ethyl acetate and gelatinous silica; cold ether, however, does not change it, although when heated to 200° with that substance, it splits up into silica and acetic anhydride. With dry ammonia it yields acetamide and hydrated silica.

Silico-acetic anhydride is analogous to Ebelmen's silicic ether, $\text{Si}(\text{OC}^2\text{H}^3)^4$, and the ethylic silico-acetin, $\text{Si} \begin{smallmatrix} (\text{OC}^2\text{H}^3)^3 \\ (\text{OC}^2\text{H}^3\text{O}) \end{smallmatrix}$, obtained by the action of acetic anhydride on silicic ether (v. 264), may be regarded as its triethylic ether.

SILICOBOROCALCITE. A mineral named *Winkworthite* by How (*Phil. Mag.* [4], xli. 270), occurring in transparent colourless nodules in the gypsum of Winkworth, Hants Co., Nova Scotia, has been shown by Kenngott (*Jahrb. f. Mineralogie*, 1872, 300) to be a mixture of silicoborocalcite and gypsum. Two analyses by How gave:

	CaO	SO [*]	SiO [*]	B ² O ³ *	H ² O
(1.) . . .	31.66	36.10	3.31	10.13	18.80 = 100
(2.) . . .	31.14	31.51	4.98	14.37	18.00 = 100

* Determined by loss.

The first contains 77.87, the second 67.75 p.c. gypsum.

SILICODIETHYL ETHER, $\text{Si}(\text{C}^2\text{H}^3)^2(\text{OC}^2\text{H}^3)^2$ (p. 1082).

SILICODIETHYL CHLORETHYLIN, $\text{Si}(\text{C}^2\text{H}^3)^2\text{Cl}(\text{OC}^2\text{H}^3)$ (p. 1082).

SILICODIETHYL CHLORIDE, $\text{Si}(\text{C}^2\text{H}^3)^2\text{Cl}^2$ (p. 1082).

SILICODIETHYL OXIDE or **SILICON-DIETHYL ESTER**, $\text{Si}(\text{C}^2\text{H}^3)^2\text{O}$ (p. 1083).

SILICONEPTYL-ACETIC ETHER, $\text{Si}(\text{C}^4\text{H}^5)(\text{OC}^2\text{H}^3\text{O})$ (p. 1083).

SILICONEPTYL CHLORIDE, $\text{Si}(\text{C}^4\text{H}^5)^2\text{Cl}$ (p. 1083).

SILICONEPTYL CARBONATE OF SODIUM, $\text{Si}(\text{C}^4\text{H}^5)^2\text{CO}^2\text{Na}$ (p. 1083).

SILICONEPTYL ETHER, $\text{Si}(\text{C}^4\text{H}^5)^2(\text{OC}^4\text{H}^7)$ (p. 1083).

SILICONEPTYL HYDRIDE, $\text{Si}(\text{C}^4\text{H}^5)^2\text{H}$ (p. 1084).

SILICONEPTYL HYDROXIDE, $\text{Si}(\text{C}^4\text{H}^5)^2\text{OH}$ (p. 1083).

SILICONEPTYL OXIDE, $\text{Si}^2(\text{C}^4\text{H}^5)^2\text{O}$ (p. 1084).

SILICON or **SILICIUM**. On the occurrence and condition of silicon in pig-iron, see pp. 695, 696.

Occurrence in Plants.—Ladenburg (*Deut. Chem. Ges. Ber.* v. 569) suggests that at least part of the silica found in plant-ashes may be produced by the combustion of organic compounds in which the carbon has been more or less replaced by silicon. Even the purest cellulose contains a small quantity of silica. The liquid remaining on dialysing the purified alkaline extract of mare's-tail (*Equisetum arvense*) left, on evaporation, pure silica, which, when burnt with copper-oxide, yielded only 1 p.c. carbon dioxide.

Apparent Volatilisation.—When the vapour of silicon chloride or fluoride is passed over silicon fused in an atmosphere of hydrogen, compounds are formed which decompose at lower temperatures, and deposit a ring of silicon on the cold part of the tube, as if the silicon had been actually volatilised (Troost a. Hautefeuille, *Compt. rend.* lxxiii. 443; *Chem. Soc. J.* [2], ix. 997; *Jahresb.* 1871, 268).

Estimation.—On the estimation of silicon in Cast iron and Steel, see IRON (p. 692). On the estimation of the Fire-resisting qualities of Clays and other Siliceous materials, see CLAY (pp. 353-357).

SILICON, HALOID COMPOUNDS OF. *Spectra.*—The haloïd compounds of silicon, heated in a hydrogen flame fed by a jet of air, give band-spectra very similar to one another, and exhibiting a predominance of green. The bands, however, do not appear to be due to pure silicon, since silicon hydride, although very volatile, does not exhibit the same bands, neither are they seen in the electric spectrum of silicon. Silicon fluoride gives only a continuous spectrum, whereas in Geissler's tubes it gives a fine band-spectrum. Silicon bromide gives in such a tube a continuous spectrum with two maxima in the yellow and the indigo, provided the electric tension is weak; with stronger tension the lines of bromine and silicon come out (*Salet, Compt. rend.* lxxiii. 1056).

Subchlorides and Oxychlorides. (Troost a. Hautefeuille, *ibid.* lxxiii. 563).—When silicon tetrachloride is passed over fused silicon contained in a porcelain tube, heated nearly to the softening point of porcelain, a liquid is obtained consisting of the tetrachloride mixed with a small quantity of the subchlorides of silicon. The tetrachloride was passed backwards and forwards five or six times over the silicon; and, to prevent decomposition of the subchlorides, a central cooling-tube traversed by a

stream of water at 60° was employed, as in Deville's experiments on dissociation (1st Suppl. 427). To prevent the formation of oxychlorides, air must be carefully excluded from the apparatus.

The tetrachloride boiling at 59° is easily separated from the other chlorides; the latter are separated from one another by repeated fractional distillation.

Trichloride, Si^2Cl^4 .—Friedel (*Compt. rend.* lxxiii. 1011) prepares this compound by gently heating the tri-iodide with mercuric chloride. It is a colourless and very mobile liquid, having a specific gravity of 1.58 at 0°. It solidifies at -1° (Friedel); at -14° (Troost a. Hautefeuille), forming large crystalline plates. It boils at 146° — 148° ; the density of its vapour, taken at 239.4° , is 9.7, corresponding with the formula Si^2Cl^4 , which requires 9.4.

When strongly heated it gives off a vapour which takes fire spontaneously in the air; heated in closed vessels, it becomes decomposed very slowly at 350° (into tetrachloride and silicon); by heating for twenty-four hours to 440° , about nine-tenths of the chloride employed is decomposed; at 800° the decomposition is complete. Trichloride of silicon is attacked by cold aqueous solution of ammonia, silica and hydrogen being produced. In contact with pure water at zero, it gives a hydrate of the sesquioxide, $\text{SiO}^2.\text{H}^2\text{O}$, identical with that obtained by Friedel a. Ladenburg from the tri-iodide (1st Suppl. 1022). This sesquioxide reduces potassium permanganate very rapidly in the cold, and chromic acid very slowly; it has no action, at ordinary temperatures, on solutions of chloride of gold or selenious acid (Troost a. Hautefeuille).

Dichloride of Silicon, Si^2Cl^4 , is a liquid which is found mixed with the trichloride, especially when the formation of the latter body is accompanied by that of highly condensed oxychlorides of silicon. Its vapour-density and boiling point have not yet been determined, as it retains pertinaciously small quantities of oxychloride. Decomposed by aqueous ammonia, it evolves a larger proportion of hydrogen than the trichloride. By contact with water at zero, it gives rise to a hydrated oxide, which reduces, not only potassium permanganate and chromic acid, but also solutions of chloride of gold and selenious acid, with separation of metallic gold and red selenium respectively (Troost a. Hautefeuille).

Oxychlorides.—Several of these compounds are produced by the action of the induction spark on a mixture of the tetrachloride, the trichlorosilicic oxide, $\text{Si}^2\text{Cl}^4\text{O}$, obtained by Friedel a. Ladenburg (1st Suppl. 1021), and oxygen, or better by passing a mixture of oxygen and trichlorosilicic oxide several times through a heated glass tube filled with fragments of porcelain. By fractional distillation of the product the following compounds have been obtained:

Empirical formula	Formula for 2 vols. according to the experimental vapour-density	Boiling point	Vapour-density at 440°
Si^2OCl^2	—	—	—
Si^2OCl^4	$\text{Si}^2\text{O}^2\text{Cl}^4$	136—139°	—
$\text{Si}^4\text{O}^2\text{Cl}^{10}$	$\text{Si}^4\text{O}^2\text{Cl}^{10}$	152—154	—
$\text{Si}^2\text{O}^2\text{Cl}^4$	$\text{Si}^2\text{O}^2\text{Cl}^4$	198—202	15.5
$\text{Si}^4\text{O}^2\text{Cl}^4$	$\text{Si}^4\text{O}^{10}\text{Cl}^{12}$	about 300	21.2
$\text{Si}^4\text{O}^2\text{Cl}^4$	—	above 400	—
$\text{Si}^4\text{O}^2\text{Cl}^4$	—	nearly 40	—

Tribromide, Si^2Br^4 . This compound is prepared by dissolving the tri-iodide in carbon sulphide, adding bromine in quantity sufficient to displace the iodine, separating the undissolved iodine by filtration, and removing the dissolved iodine by agitation with mercury. The liquid on evaporation yields crystals of the tribromide, which are doubly refractive, and may be distilled without decomposition at about 240° . On treating it with potash, hydrogen is evolved in the proportion of H^2 to each molecule of Si^2Br^4 (Friedel, *Compt. rend.* lxxiii. 1011).

Chlorobromides. The *trichlorobromide*, SiCl^3Br , is formed by the action of bromine on silicic chloroform, SiCl^3H . It is a colourless fuming liquid, which boils at 80° , is decomposed by water, and exhibits great similarity to silicon tetrachloride.

The *dichlorodibromide*, SiCl^2Br^2 , is also formed by the action of bromine on silicic chloroform, and is found among the products boiling at about 100° (Friedel a. Ladenburg, *Ann. Chim. Phys.* [4], xxvii. 416).

Chlorosulphhydrate, SiCl^3SH . This compound, analogous in composition to methylic mercaptan, CH^3SH , was regarded as a sulphochloride by Pierre, who obtained it by passing a mixture of the vapour of silicon tetrachloride and hydrogen sulphide through a red-hot tube (v. 270). It is a colourless liquid boiling at 66° , and having a mixed odour of hydrochloric acid and sulphydric acid, these two acids being formed, together with silica, when it is exposed to the air. When three molecules of alcohol

are made to react on one molecule of silicon chlorosulphhydrate, an evolution of hydrochloric acid takes place, and the compound, $\text{SiSH}(\text{OC}^2\text{H}^5)_2$, appears to be produced; but if either this compound or the original silicon chlorosulphhydrate be treated with excess of alcohol, a reaction resulting in the formation of silicic ether, $\text{Si}(\text{C}^2\text{H}_5\text{O})_4$, takes place. Bromine decomposes silicon chlorosulphhydrate, with formation of the trichlorobromide, $\text{SiSHCl}^3 + \text{Br}^2 = \text{SiBrCl}^3 + \text{SiBr} + 2\text{HBr}$ (Friedel a. Ladenburg, *loc. cit.*)

Silicon Subfluoride is a white, very light powder produced by passing the tetrafluoride over silicon heated nearly to the softening point of porcelain. It is probably a trifluoride, as in contact with water it yields a hydrated oxide which exhibits the same characteristic reactions as that which is formed in like manner from the trichloride (Troost a. Hautefeuille, *Compt. rend.* lxxiii. 563).

SILICOPROPIONIC ACID, $\text{Si}(\text{C}^2\text{H}^5)_3\text{O}^2\text{H}$ or $\text{CH}^3\text{—CH}^2\text{—SiO}^2\text{H}$ (see **SILICIC ETHERS**, p. 1082).

Orthosilicopropionic Ethyl-ether, $\text{Si}(\text{C}^2\text{H}^5)(\text{OC}^2\text{H}^5)_2$, formed by the action of zinc-ethyl and sodium on tetramethyl silicate, boils at 159° (p. 1082).

Orthosilicopropionic Methyl-ether, $\text{Si}(\text{C}^2\text{H}^5)(\text{OCH}^3)_2$, is formed in like manner by the action of zinc-ethyl and sodium on tetramethyl silicate:

The orthosilicopropionic methyl-ether, purified by fractional distillation, boils at $125^\circ\text{—}126^\circ$, and has a specific gravity of 0.9747 at 0° . It resembles the corresponding ethyl-compound in odour and appearance, but is more easily decomposed by water, ammonia, &c. Hydriodic acid boiling at 127° acts violently on it, separating a solid body. When left in contact with water it undergoes decomposition, which is accelerated by addition of ammonia. The product of the reaction is a translucent jelly which dries up to a white powder of nearly pure silicopropionic acid (Ladenburg, *Deut. Chem. Ges. Ber.* vi. 1081).

Tetraethyl silicate, zinc-methyl, and sodium do not act on one another at ordinary temperatures. When tetraethyl silicate is heated with zinc-methyl (without sodium) to a temperature above 300° , crystals of the compound $\text{Zn}(\text{CH}^3)(\text{OC}^2\text{H}^5)_2$ are obtained, and the silicic ether formed at the same time yields by decomposition a combustible silicic acid, probably *silico-acetic acid* (Ladenburg, *loc. cit.*)

SILICOTETRETHYL, $\text{Si}(\text{C}^2\text{H}^5)_4$ (p. 1084).

SILICOTRIETHYL BROMIDE, $\text{Si}(\text{C}^2\text{H}^5)_3\text{Br}$ (p. 1083).

SILICOTRIETHYL CHLORIDE, $\text{Si}(\text{C}^2\text{H}^5)_3\text{Cl}$ (p. 1083).

SILICOTRIETHYL OXIDE, $\text{Si}^2(\text{C}^2\text{H}^5)_6\text{O}$ (p. 1084).

SILVER. *Occurrence and Extraction.*—On the occurrence of silver and gold ores in California, and on Rivot's method of working them, see **GOLD** (p. 572).

On Tessié du Mothay's method of extracting silver and gold from arseniosulphides of lead, copper, &c., see p. 573.

On Stetefeldt's furnace for the roasting and chlorination of silver ores, see *Dingl. pol. J.* cxvii. 244.

On Kröncke's method of amalgamating silver ores, see L. Eich (*Chem. Centr.* 1871, 121; *Chem. Soc. J.* [2], ix. 447).

The chemical processes in the amalgamation of gold and silver ores in Washoe are described by A. Hague (*American Chemist*, iii. 98; *Jahresb. f. Chem.* 1872, 951).

Claudet has devised a process for the extraction of silver from copper pyrites. The lyes obtained by treating the pyrites, after roasting and chlorination, with water, usually contain 1 pt. of silver to 10,000 pts. of copper. To separate the silver the solutions of the chloride are mixed with a metallic iodide, best with iodide of potassium; and the deposition of the silver iodide is facilitated by diluting the solution till slimy; and the deposition of the silver iodide is ensured by blowing in steam. The precipitate thus formed contains silver iodide, cuprous chloride, cupric oxychloride, and small quantities of lead and iron. The other salts are removed by dilute hydrochloric acid; the silver iodide is treated with metallic zinc; and the solution of zinc iodide decanted from the reduced silver is used for precipitating the silver from a fresh portion of the crude liquor (*Mechanic's Magazine*, Sept. 1870, p. 207). A favourable report of the results of this process is given by J. A. Phillips (*Chem. News*, xxii. 184).

Preparation of Pure Silver.—Grüger (*Dingl. pol. J.* cciii. 111, 292) prepares pure silver from an alloy of silver and copper by heating the solution of the alloy in nitric acid to 70° , and adding calcium carbonate (levigated chalk) as long as effervescence takes place. The whole of the copper is thereby precipitated, while the silver re-

mains in solution together with calcium nitrate. This solution is either precipitated with sodium carbonate, the precipitate ignited and then exhausted with hydrochloric acid, which leaves the silver in the metallic state; or it is digested with silver oxalate, whereby the calcium is separated, and pure silver nitrate remains in solution.

J. Krüger (*ibid.* cxi. 243) prepares pure silver from silver residues, by mixing them with phosphoric ether and repeatedly shaking the mixture. The whole of the silver is then obtained as a black precipitate; and on filtering, washing, and drying, or boiling the still moist precipitate in a porcelain basin with caustic potash, pure metallic silver is left undissolved. To obtain a solid regulus, the dried precipitate is gradually added to potassium carbonate melted in a crucible.

Gladstone & Tribe (*Chem. News*, xxiv. 76) describe the growth of silver crystals during the action of a plate of copper on a solution of silver nitrate.

According to Tribe (*ibid.* xxiv. 135) silver precipitated by copper always contains copper; if, as is generally the case, the solution has absorbed air. If, on the other hand, the air be expelled by carbonic acid, the amount of copper in the precipitated silver is extremely small.

According to C. F. Chandler (*ibid.* xxiv. 10) silver nitrate is immediately reduced to metallic silver by glowing charcoal, the reduced silver penetrating the charcoal and taking the place of the particles of carbon consumed in the reduction, so that it exhibits the exact structure of the original wood.

On Gräber's method of reducing silver from an ammoniacal solution of the chloride with zinc, see *Chem. Soc. J.* [2], ix. 499. On the recovery of silver nitrate from the silver-bath, and from the residues obtained in electroplating, see Gräber, *ibid.* 500.

On the precipitation of silver by ferrous sulphate from the solution of silver sulphate obtained in the 'parting' of gold and silver, see Gützkow (*Deut. Chem. Ges. Ber.* iv. 114; *Chem. Soc. J.* [2], ix. 448).

On the alteration undergone by silver vessels, &c., long buried in the earth, see Church (*Chem. Soc. J.* [2], ix. 498) and Schortel (*ibid.* 666).

Estimation and Separation of Silver.—On the estimation of silver in presence of mercury, see Debray (*Compt. rend.* lxx. 840, 995; *Jahresh. f. Chem.* 1870, 1014).

On the assaying of silver, see Tookey (*Chem. News*, xxi. 246), Blossom (*ibid.* xxiv. 14, 42, 269), and Busted (*ibid.* xxiv. 243, 259).

On the separation of silver from copper, see COPPER (p. 388).

Quantivalence of Silver.—Wislicenus (*Deut. Chem. Ges. Ber.* iv. 63) regards silver (at. w. = 108) as bivalent, on account of the constitution of the argentous salts, of the silver-compounds of acetylene and its homologues, and of the idonitrate of silver, Ag^2INO^4 (prepared by prolonged heating of a concentrated solution of silver nitrate in nitric acid with silver iodide, p. 860), and of the corresponding bromonitrate. On this view of the quantivalence of silver, many of its compounds may be represented by formulæ exactly analogous to those of cuprous compounds, with which they are isomorphous; *ej.*

SILVER, HALOID SALTS OF. On the refraction and dispersion of light by silver chloride, bromide, and iodide, see *LIGHT* (p. 742).

On the chemical and mechanical changes produced by light in the haloid compounds of silver, see C. Schultz-Sellack (*Deut. Chem. Ges. Ber.* iv. 210, 343; *Chem. Soc. J.* [2], ix. 302, 481).

Reactions with Mercury Salts.—Preuss observed that silver iodide dissolves abundantly in a solution of mercuric nitrate, the solution solidifying on cooling to a crystalline mass consisting of a double compound of silver iodide and mercuric nitrate, $4\text{AgI} \cdot 2\text{HgN}^2\text{O}^6 + \text{H}_2\text{O}$ (*Gmelin's Handbook*, vi. 199). Afterwards Wackenroder (*ibid.* 159, 165) observed that the bromide and chloride of silver likewise dissolve readily in aqueous mercuric nitrate; and Liebig found that a warm solution of silver chloride in mercuric nitrate deposits, on addition of water and cooling, shining crystals of silver chloride (*Ann. Ch. Pharm.* lxxi. 128). These statements have been confirmed in their essential particulars by Debray (*Compt. rend.* lxx. 995), who further states that iodide and bromide of silver crystallise, on cooling, from a hot solution of mercuric nitrate. He also confirms the statement of Risse (iv. 104) that silver chloride dissolves in aqueous silver nitrate, but he was not able to obtain the definite compound of the two mentioned by Risse, the crystals which separated from the hot saturated solution consisting simply of silver chloride.

Chloride, AgCl. According to Stas (*Compt. rend.* lxxiii. 998), this compound exists in four different states: 1. gelatinous; 2. curdy-flocculent; 3. pulverulent; 4. granulo-sealy-crystalline, as obtained by fusion. In the last-mentioned state, its solubility in water at ordinary temperatures = 0, or at least does not attain the limit at which dissolved silver chloride can still be recognised, a limit which Stas fixes at 1 part in ten million. Its solubility in boiling water is proportionally great, but diminishes rapidly as the temperature falls, and is equal to nothing at 16° . The curdy modification obtained by precipitation from cold dilute solutions is the most soluble, but its solubility diminishes as the flocks spontaneously condense, or when the precipitate is rendered pulverulent by agitation. A solution of flocculent or pulverulent silver chloride in pure water, or water acidulated with nitric acid, is precipitated both by silver nitrate and by hydrochloric acid. To precipitate a unit of silver or of chlorine in the state of dissolved flocculent or pulverulent silver chloride requires 3 units of chlorine, or of silver (as nitrate). The precipitation is always complete. The salts formed in the reaction simultaneously with the silver chloride have no influence on the solubility of the chloride in pure or acidulated water. The presence of nitric acid does not increase the solubility of curdy or flocculent silver chloride, whereas that of the pulverulent variety increases in proportion to the quantity of nitric acid contained in the water. Saturated solutions of granular silver chloride are likewise precipitated both by chlorine and by silver nitrate, and the precipitation of a unit of silver or of chlorine, as silver chloride, likewise requires 3 units of chlorine or of silver, but the separation of the dissolved granular silver chloride is never complete.

With hydrobromic or hydriodic acid the precipitation may always be so conducted that the liquid shall not give a precipitate either with silver nitrate or with a haloid salt.

Pierre (*Compt. rend.* lxxiii. 1090) observes that when solution of silver nitrate is added drop by drop to concentrated hydrochloric acid, the precipitate formed disappears so rapidly that it sometimes escapes observation altogether. The weight of the silver chloride dissolved may exceed one-half p.c. of the weight of the hydrochloric acid employed. The subsequent addition of water very slowly reprecipitates the whole of the chloride.

When nitric acid is distilled over a small quantity of silver chloride, in the state of powder, the latter disappears gradually; this is, however, not a simple solution, because, at the end of the operation, crystallised silver nitrate is found in the retort instead of the chloride.

Thorpe (*Chem. Soc. J.* [2], x. 453) finds that 100,000 pts. of strong nitric acid dissolve about 2 pts. of pure, white silver chloride, and that the solubility is not sensibly affected by the presence of lower oxides of nitrogen in the acid, but that as the chloride darkens by exposure to light, less of it is taken up by the acid, 100,000 pts. of the acid dissolving only 0.8 pt. of the blackened silver chloride.

Fluoride, AgF. The following observations on this compound have been made by Gore (*Proc. Roy. Soc.* xx. 70), in addition to those reported in the 1st *Suppl.* (p. 1027).

The action of iodine and heat on silver fluoride produces iodine fluoride (a volatile, colourless, fuming liquid) and silver iodide, also, if the temperature approaches redness, corroding the platinum vessels and forming a double salt of silver iodide and platinum fluoride.

Silver fluoride is reduced by heating in dry *cyanogen vapour*, or *hydrogen cyanide*, or *coal gas*, but is unaffected by carbon oxide or dioxide, silicon fluoride, sulphur dioxide, or sulphur fluoride vapour, or by liquid cyanogen, carbon bisulphide, hydrocyanic acid (anhydrous), carbon tetra- or trichloride, pure carbon, or boron crystals. Fused in the vapour of *carbon tri- or tetrachloride*, it forms silver chloride, as well as an insoluble double salt of silver and platinum by corrosion of the vessels. A solution of bromine or iodine in carbon tetrachloride or bisulphide is quickly decolorised by agitation with silver fluoride. The fluoride is also decomposed violently by fusion with vitreous boric acid, silicon, dry silica, or sulphur. In the latter case sulphur fluoride, a heavy colourless gas of a peculiar dusty odour, is evolved. *Sulphur chloride* with silver fluoride, either fused or in solution, gives silver chloride and vapour of sulphide. *Carbon bisulphide* at a red heat yields silver sulphide and carbon tetrafluoride, $4\text{AgF} + \text{CS}_2 = \text{CF}_4 + 2\text{Ag}_2\text{S}$.

Carbon tetrafluoride is also said to be formed when silver fluoride is added to liquid carbon bisulphide containing bromine or iodine in solution.

Iodide. AgI. According to A. Vogel (*N. Rep. Pharm.* xx. 120), silver iodide is not decomposed by boiling aqueous potash, the grey colour which it acquires being due to molecular alteration; native silver iodide from Mexico exhibits a similar colour. Even by fusing silver iodide with potassium iodide, only a very incomplete decomposition is effected, and the separation of metallic silver from it by zinc and hydrochloric acid is less complete than in the case of the chloride. When dry silver chloride is triturated with pulverised iodine, and the excess of iodine removed after some time by solution in alcohol, the chloride of silver is found to be partly converted into iodide, and no longer dissolves completely in ammonia. Silver iodide is partly decomposed by a strong heat, with evolution of iodine. In closed vessels it volatilises at a white heat.

On the compounds of silver iodide with silver nitrate, see NITRATES (p. 860).

SILVER OXIDES. To decide whether the alkaline reaction of silver oxide is due to adhering alkali, or belongs to the oxide itself, A. Vogel (*N. Rep. Pharm.* xx. 93) precipitated an acid solution of silver nitrate with lime-water, keeping the silver nitrate in excess, and washed the precipitated silver oxide thoroughly with hot water. The still moist oxide, laid upon reddened litmus paper, immediately produced a distinct blue spot, and on recently prepared turmeric paper a brown spot. Silver nitrate also, especially after fusion, has, according to Vogel, an alkaline reaction. Crystals of silver nitrate lose their acid reaction and become alkaline when their solution is boiled with silver foil or silver oxide.

Peroxide, Ag_2O_2 .—For the preparation of this oxide, Böttger (*Zeitschr. f. Chem.* [2], vi. 82) recommends the electrolytic method employed by Ritter (v. 303). The peroxide sets fire to hydrogen sulphide and oil of cloves, and eliminates nitrogen from aqueous ammonia, as formerly observed by Grothuss (*Jahresb.* 1852, 423). When it is triturated with gold sulphide, the mixture quickly takes fire.

SILVER SULPHIDES. A double sulphide of silver and iron, called *silver pyrites*, occurring with proustite in the mineral veins of Joachimsthal, forms, according to S. von Waltershausen (*Jahrbuch. f. Min.* 1868, 725), very small monoclinic crystals of hexagonal character. Colour, light lead-grey with a tinge of yellow; streak black; brittle; fracture uneven; hardness = 3·5; sp. gr. = 6·47. An analysis made with a very small quantity of material gave 39·3 p.c. Fe, 26·6 Ag, and 34·2 S, agreeing with the formula $\text{Ag}_3\text{S}_2\text{FeS}_2$. According to Tschermak, however (*ibid.* 726), silver pyrites is not a distinct mineral species, but a pseudomorph (consisting of marcasite, pyrrhotin, argentite, and pyrrargyrite), and probably identical with Zippe's pseudomorph of iron pyrites after pyrrargyrite and stephanite. On the other hand, A. Schrauf (*ibid.* 1872, 94) maintains that the mineral is not a pseudomorph, but a distinct species, crystallising in the rhombic system, and isomorphous with stannbergite. He found the specific gravity to be 6·53 at 13°, and the amount of silver 21·2 and 22·3 p.c. the above formula requiring 24·77 p.c.

On the *sulphide of silver and gold*, $5\text{Ag}_2\text{S} \cdot 2\text{Au}_2\text{S}_3$, discovered by Muir, see GOLD (p. 576).

SINOWITE. *Blodite*.—A sodio-magnesian sulphate, $\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 + 4\text{H}_2\text{O}$, occurring in the carnallite of Stassfurt (*Jahresb. f. Chem.* 1871, 1181; 1872, 1141).

SINALBIN, $\text{C}^8\text{H}^4\text{N}^2\text{S}^2\text{O}^{14}$. A constituent of the seed of white mustard. See MUSTARD (p. 832).

SINNIGONITE. Syn. with POTASSIUM MYRONATE (iii. 1079).

SNARUMITE. This name is given by Breithaupt (*Jahrb. f. Min.* 1872, 330).

to a mineral from Snarum in Norway, agreeing in composition with spodumene, but differing from it (being micaceous) in physical properties:

SiO_2	Al_2O_3	Fe_2O_3	Mn_2O_3	CaO	Na_2O	Li_2O	Loss by ignition
67.42	28.21	0.42	0.18	0.24	09.3	2.15	0.23 = 99.78.

SODA. On the composition of Crude Soda, and the loss of Sodium in Leblanc's process, see Scheurer-Kestner (*Compt. rend.* lxx. 1352; *Jahresb. f. Chem.* 1870, 114); also Maclear (*Chem. News*, xxv. 54; *Jahresb.* 1872, 975).

On the quantity of Arsenic introduced into the products of the soda-manufacture from the pyrites used for the preparation of sulphuric acid, see H. A. Smith (*Chem. News*, xxiii, 221; *Jahresb.* 1871, 1014).

On the recovery of Sulphur from Soda-waste, see L. Mond (*Dingl. pol. J.* cii. 266; *Jahresb.* 1871, 1015), Stahlschmidt (*Dingl. cv.* 229; *Jahresb.* 1872, 977).

Buchet's process for preparing caustic soda by decomposing common salt with litharge and lime is described by R. C. Clapham (*Chem. News*, xxi, 148; *Jahresb.* 1870, 1114); further by Clapham & Ball (*American Chemist*, iii, 181; *Jahresb.* 1872, 978).

A method of preparing *silicate of soda* by decomposing common salt with silica and aqueous vapour is given by A. Ungerer (*Dingl. pol. J.* xcvi. 343; *Jahresb.* 1870, 1118).

SODIUM. On the solubility of sodium in liquid ammonia, see p. 60.

Bromide, NaBr.—Castelholz (*Compt. rend.* lxx. 1050) prepares this salt by decomposing ammonium bromide with an equivalent quantity of pure hydrate or carbonate of sodium. The ammonium bromide is prepared by dropping bromine into pure dilute ammonia, and purified from the much more soluble iodide by recrystallisation.

Chloride, NaCl.—On the crystallisation of this salt in transparent cubes from solutions containing ferric chloride, magnesium chloride, &c., see Buchner (*N. Rep. Pharm.* **xx**, 151; *Jahresb.* 1871, 274; *Chem. Soc. J.* [2] **ix**, 311).

Hydrate, NaHO .—O. Hermès (Pogg. Ann. cxix. 170; Dent. Chem. Ges. Ber. iii. 122) observed that a solution of caustic soda, of sp. gr. 1.365, deposits the hydrate at low temperatures in crystals having the composition $2\text{NaHO} \cdot 7\text{H}_2\text{O}$. These crystals were described in 1863 by G. Rose, who regarded them as monoclinic. According to Hermès, however, they are rhombic prisms of 98° slightly truncated on the acute lateral edges. They are transparent and colourless, with a vitreous lustre, melt at 6° , and separate tolerably pure from a solution of caustic soda containing chlorido, sulphate, and carbonate of sodium.

SOLFATARAS. On the gases evolved from the solfataras of Vesuvius and the Campi Flegrei, see GASES (p. 550).

SORBIC ACID, C⁶H⁸O². This acid, which Hofmann obtained from unripe mountain-ash berries (p. 352), has been further examined by Burringcr n. Fittig (*Zeitsch. f. Chem.* 1870, 426; *Ann. Ch. Pharm.* clxi. 307) with the view of determining whether it is analogous in its chemical relations to the acids of the series C⁴H⁴-CO², or C⁶H⁸-².COOH (palmitolic, stearolic, lichenolic). These chemists confirm Hofmann's statements with regard to the properties of sorbic acid, excepting as to its alleged capability of volatilising without decomposition. They find indeed that the pure acid begins to boil at 226°, part of it distilling unaltered at this temperature, while the rest is converted, with emission of a distinct odour of acrolein, into a very thick brown mass, hardening on cooling to a resin, from which sorbic acid is not regenerated by boiling with water.

When 1 mol. sorbic acid is triturated under water with 2 mols. bromine, a semifluid mass is obtained, consisting of the solid tetrabromide of sorbic acid, $C_8H_6Br_4O_2$ —isomeric or identical with tetrabromocaproic acid, and a liquid which is probably the dibromide $C_8H_8Br_2O_2$. On dissolving the crude product in hot alcohol, and leaving the solution to cool, or allowing the alcoholic solution to evaporate spontaneously, a thick oil is obtained which, when separated from the mother-liquor, solidifies, for the greater part, in a few days. By pressing the product, dissolving it, and repeating these operations several times, the tetrabromide is finally obtained in large well-defined, apparently monoclinic crystals, which are transparent, have a vitreous lustre, and no longer separate from hot alcohol in the liquid state. This compound is very sparingly soluble in water even at the boiling heat, and crystallizes therefrom in capillary needles. It melts at 178° – 179° , dissolves in alkaline carbonates, and is precipitated therefrom by acids without alteration.

Hydroxysorbic Acid, $C^6H^8O_6$. This acid, belonging to the oleic series, and isomeric with pyrotarabic and ethyl-crotonic acid, is easily formed by treating sorbic acid with water and sodium-amalgam. It is a colourless liquid having a peculiar

odour of perspiration and slightly soluble in water. Sp. gr. = 0.969 at 10°. Boiling point 201° (204°-205° corr.) Remains liquid at -18°.

Calcium Hydrosorbate, $(C^4H^4O^2)^2Ca + H^2O$, crystallises easily in groups of small, very soluble needles. The **barium salt**, $(C^4H^4O^2)^2Ba$, crystallises in very beautiful anhydrous needles having a silky lustre, easily soluble in water. The **copper salt**, $(C^4H^4O^2)^2Cu$, is a greenish-blue precipitate which loses part of its acid at 100°, and melts to a deep green liquid at 180°-185°. The **silver salt**, $C^4H^4O^2Ag$, is a white precipitate insoluble in water, turning brown at 90°-100°. The **ethyl ether**, $C^4H^4O^2C^2H_5$, is a colourless liquid, having a fruity odour, boiling at 166°-167°; slightly soluble in water.

Bromine acts violently on hydrosorbic acid at ordinary temperatures, with evolution of hydrogen bromide, but at low temperatures the additive compound, $C^4H^4O^2Br^2O^2$, hydrosorbic dibromide or dibromo-caproic acid, is formed. It is a colourless viscid liquid insoluble in water, reconverted by alcoholic potash into sorbic acid.

Hydrosorbic acid is not altered by heating it with *potassium hydrate* to 180°; but if the heat be raised till gas begins to be evolved, carbonic and butyric acid are formed, but no other acid of the fatty series.

Constitution of Hydrosorbic and Sorbic acids.—Fittig and Barringer represent hydrosorbic acid by the formula :

which accords best with its behaviour with fused potash, whereby the group $\text{CH}=\text{CH}^2$ is split off and replaced by hydrogen, producing butyric acid, $\text{CH}^2-\text{CH}^2-\text{CH}^2-\text{COOH}$, while the group $\text{CH}-\text{CH}^2$ itself is oxidised to oxalic and finally to carbonic acid.

Sorbic acid may be represented by the formula :

which explains its probable resolution by distillation into two molecules of acrolein, $\text{CH}^2=\text{CH}-\text{COH}$, and is analogous to that proposed by Fittig for sorbin, viz.:

Barringer and Fittig doubt the existence of Hofmann's *parasorbic acid*, and conclude from their experiments that it was nothing but impure sorbic acid. Hofmann describes it as a liquid having less decided acid properties than sorbic acid, and dissolving in alkaline carbonates without evolution of carbonic acid. Barringer and Fittig, however, find that it dissolves in warm sodium carbonate with violent evolution of carbonic acid, and that the filtered solution, concentrated and mixed with hydrochloric acid, yields pure crystalline sorbic acid.

SORBIN, $C^4H^{10}O^4$.—A sugar, isomeric with glucose, obtained from the fermented juice of mountain-ash berries (v. 352).^{*} Pelouze, who discovered it, was unable to decide whether it existed ready formed in the fruit, or was a product of decomposition. Byschl (*Jahresh. f. Chem.* 1854, 664) found no sorbin in the juices of ripe mountain-ash berries; and Delffs (*Chem. News*, xxiv. 75; *Jahresh.* 1871, 799) has observed that no sorbin is obtained when an attempt is made to combine the preparation of malic acid from the berries with that of sorbin, the malic acid being for that purpose precipitated by lead acetate before the preparation of sorbin by Pelouze's process is commenced. When the latter process is strictly followed, a large quantity of sorbin crystals is obtained, but no malic acid is found in the fermented juice. Delffs therefore supposes that there is an intimate connection between the disappearance of the malic acid and the formation of sorbin, which may perhaps be represented by the equation :

At all events, sorbin does not exist ready formed in the berries of the mountain-ash.

Sorbin, treated with *bromine* and water, is oxidised to glycollic acid (Hlasiwetz and Habermann, *Ann. Ch. Pharm.* clv. 120).

SORBITE, $C^4H^{10}O^6$ (Boussingault, *Compt. rend.* lxxiv. 939). A non-fermentable sugar, isomeric with mannite and dulcete, obtained from the juice of mountain-ash

^{*} There called *sorbin*; but this latter name is now applied to a sugar isomeric with mannite, likewise obtained from mountain-ash berries (see the next article).

berries. It may be separated from the fermented juice, but is not a product of fermentation, since it may also be obtained from the fresh juice immediately after expression.

Sorbitol is nearly insoluble in cold alcohol, moderately soluble in boiling alcohol, from which it separates on cooling in translucent, opalescent, warty masses. From aqueous solution it is obtained in nacreous crystals which have the composition $2C^6H^{14}O^6.H^2O$, and give off their water of crystallisation when heated above 100° . It differs from mannitol and dulcitol by several properties. It melts in the hydrated state at 102° , in the anhydrous state at 110° – 111° , whereas mannitol melts at 165° and dulcitol at 182° . With water it forms a syrupy solution which, after some time, deposits crystals, whereas an aqueous solution of mannitol has no syrupy consistence. The crystals of sorbitol are so thin that their form is difficult to determine, whereas mannitol forms quadratic prisms, and dulcitol oblique rhombic prisms (sorbitol also forms well-defined crystals, v. 352, 353). It is inactive to polarised light, and does not reduce an alkaline cupric solution. Sulphuric acid does not carbonise it, even with the aid of heat, but dissolves it, the solution neutralised with barium carbonate yielding insoluble barium salts.

SPECTRAL ANALYSIS. There appears to be little doubt that differences in the molecular structure, as in the case of allotropic modifications of the elements, and also in the case of compound bodies, are accompanied by distinct differences in the spectra of these substances. From a theoretical point of view this would appear likely, as the vibrations taken up or given out by a complicated system of molecules must be different from those absorbed or emitted by a simpler system. The peculiar differences between the spectra of elementary bodies and of compounds has already (1st Suppl. 1031) been pointed out. The characteristic of the compound-spectrum, as seen at temperatures below the point of dissociation, is that it consists of bands or maxima of light, each containing rays of more than one degree of refrangibility; whilst that of the elementary-spectrum is the existence of fine lines, each of which, as a rule, contains light of one degree of refrangibility only. These definitions, however, do not hold good universally; thus in the spectra of many metals, such as Al, Pb, Mn, Cl, Sn, Zn, Sb, and Ba (Lockyer, *Phil. Trans.* 1873, Part I. plates 11, 12), broad bands occur which are especially seen as lines winged at the poles, and the absorption-spectra of certain compounds, as those of the higher oxides of nitrogen, are chiefly made up of masses of the finest lines and are not banded.

It may, however, be admitted (with Lockyer, *Proc. Roy. Soc.* June 11, 1874) that the first stage of molecular complexity corresponds with the line-spectrum; that the second stage is represented by the channelled-space-spectrum; and that the third stage corresponds with a continuous spectrum (whether emissive or absorptive). Lockyer (*loc. cit.*) proposes to extend the comparison still further, as he interpolates two other stages after that of the channelled spaces—(a) in which the general absorption begins at the blue end and does not extend into the least refrangible rays, (b) in which the general absorption begins in the red, not reaching to the blue. The three divisions as above given appear, however, to be as many as can safely be relied upon, and we should do well to remember Kirchhoff's caution respecting change of the spectra with change of luminosity (1st Suppl. 1032).

As a rule, too, it may be admitted that the spectra of compounds contain more bands than those of the elements, but no sharp distinction can be drawn even here. Thus, for instance, certain lines, as those of sodium and hydrogen, widen under certain conditions; and that this widening cannot be explained by the supposition that the gas is becoming of a more complicated molecular structure, is shown by the fact that these bands make their appearance at a temperature higher than that at which the lines are frequently seen; thus when the Leyden jar is interposed in the circuit of a Geissler's tube containing hydrogen, the lines are widened, and here it is evident the temperature cannot be lower than when the narrow lines were seen without the jar.

As regards the existence of more than one spectrum for any given elementary body, we have in the case of sulphur two spectra; a continuous one to begin with, which breaks up on heating into a second spectrum of channelled spaces. In the case of oxygen we should expect that the absorption-spectrum of the denser ozone would exhibit a difference from that of ordinary oxygen, but observations on this point have hitherto not been made. The spectrum of nitrogen has recently been much worked upon, without, however, completely solving the question of its dual spectrum (*ibid.* i. 1031). When the spectrum of nitrogen containing a trace of air or oxygen is examined in a vacuum-tube, the characteristic channelled spaces usually called the nitrogen bands are invariably seen. If now the gaseous contents of the tube be freed from oxygen and vapour of water by heating some metallic potassium or sodium in the tube, these bands never again appear (Schuster, Stearn, Willner). The lines which make their appearance after the sodium has been heated in the gas seem to vary with the mode in which the experiment is conducted; thus Willner obtained the carbonic-acid-spectrum

(perhaps from the grease of his glass stopcocks); Stearn saw the acetylene-spectrum (probably because he used sodium which had been in contact with rock-oil); and Schuster saw only the hydrogen lines (his sodium never having been in contact with oil). The fact that the lines of hydrogen appear, whilst no nitrogen lines are seen, is certainly very remarkable, and cannot be easily explained; for a mixture of air and hydrogen always gives the air- as well as the hydrogen-spectrum. Thus ammonia gas collected with great care, and decomposed by the spark, always shows the air-band together with the hydrogen lines. It is possible that the nitrogen lines are not seen by reason of the bad conductivity of the gas, and the most probable supposition (in spite of the experiments and conclusions of Willner and Salet) appears to be that the ordinary band-spectrum of nitrogen is that of an oxide. At any rate, if this is due to nitrogen itself, this substance must exist in three allotropic modifications, for the band-spectrum consists of two different spectra, the red bands and the blue bands. These two spectra can readily be separated so that one tube shows only the red and another only the blue bands, the former corresponding with a higher temperature than the latter. As regards hydrogen there can be no doubt that Angström's opinion (*ibid.* 1032) is correct, and that only one spectrum of hydrogen is known.

Goldstein (*Phil. Mag.* [4], 49, p. 333) has recently come to the conclusion, in opposition to Willner's views, that the change from a band- to a line-spectrum in the case of gaseous spectra is to be ascribed rather to a change of temperature than to a change of density in the gas.

Absorption-Spectra of the Metals.—New absorption-spectra of the metals sodium and potassium have recently been observed by Roscoe and Schuster (*Proc. Roy. Soc.*, June 11, 1874), who examined the absorption of the vapours of these metals at low temperatures, first heated in glass—and afterwards in iron tubes. These new spectra are of a complicated character, consisting of several splendid series of channelled spaces both in the red and blue portions of the spectrum; that these are caused by the vapour of the metals in question, and not by any oxide, is proved by the facts that the metal contained in the sealed glass tubes was frequently melted and allowed to stand until the surface remained perfectly bright and metallic, showing absence of every trace of oxygen; also that when the metals were heated in an iron tube filled with hydrogen the peculiar bands disappeared at once when air was admitted. The following numbers give the wave-lengths of the chief bands of these two spectra in tenth-metres.

Bands of potassium shaded off towards red:—

6844	6450	6311	5949	5763
6762	6430	6300	5930	5745
6710	6400	6275	5901	5732
6666	6370	6059	5860	5712
6615	6357	6033	5842	5700
6672	6350	6012	5821	5690
6534	6331	5988	5802	5674
6494	6322	5964	5781	5667

Absorption bands of sodium, wave-lengths in tenth-metres:—

5668	6361	6105	5999	4964
5616	6272	6092	5150	4927
5552	6235	6071	5120	4880
5499	6192	6051	5082	4863
5450	6162	6035	5038	4832
5405	6149	6016	5002	4810

From this we see that each of the alkaline metals exhibits two distinct absorption-spectra, one consisting of channelled spaces and one of dark lines coincident with the ordinary emission-spectrum of the metal.

Lockyer & Roberts (*Proc. Roy. Soc.* xxiii. 354) have obtained absorption-spectra of several heavy metals by volatilizing them in a lime crucible heated by the oxygen-hydrogen flame, and they thus found that, in addition to the well-known spectra, channelled-space-spectra are produced by the vapours of certain metals, and such spectra are produced by vapours which are competent to give, at other times, not only line-spectra, but continuous spectra in the blue or blue and red.

Metallic Spectra.—A most remarkable feature in the spectra of metals has been pointed out by Lockyer (*Phil. Trans.* 1873, 233), viz. that when the electric-spark-spectrum of any metal—say of iron—is examined by throwing an image of the electrodes on to the slit of the spectroscope, a difference in length of the several metallic lines is observed; and in this way, that the brightest of the metal lines is invariably the longest. In other words, the vapours close to the electrodes

give lines which disappear at a greater distance from the electrode, causing the appearance of long and short lines in the spectrum. The length of the lines appears to depend on the pressure to which the vapour is subjected; thus the lines gradually disappear when the pressure is reduced (the electrodes being inclosed in glass tubes), the shorter lines disappearing first and the longest lines remaining longest visible. When the metals are combined with a metalloid (chlorine, for instance) the spark-spectrum of the compound exhibits only the longest and brightest of the metal lines, all the shorter lines (as is the case under diminished pressure with the metal alone) having disappeared. The proportion of the metal lines seen in the spark-spectrum of the compound appears to be connected with the atomic weight (or, more probably, with the volatility) of the metal; thus 60 p.c. of the lines of lithium are seen in the spectrum of the chloride of lithium, whereas 8 p.c. of the barium, and only 3 p.c. of the lead, lines are seen under like conditions (Lockyer).

A valuable contribution to our knowledge of metallic spectra has recently been made by Thalen (*Kongl. Svenska. Vet. Akad. Handl.* Bd. 13, No. 4, 1874), in his accurate maps of the spectra of Yttrium, Erbium, Didymium, and Lanthanum.

Applications to Solar Chemistry.—Lockyer applies these observations to elucidate the peculiarities of the solar spectrum. It is well known that all the lines of the metallic elements in the solar atmosphere are not reversed, but without exception those lines which are found to be reversed are the *longest lines*. Applying this discovery Lockyer has added the following metals to the last list of solar elements given by Thalen: 1. (*Proc. Roy. Soc.* Dec. 12, 1872) zinc (rejected by Thalen from Kirchhoff's first list); 2. (*ibid.*) aluminium (rejected both by Kirchhoff and Thalen); 3. (*ibid.* Nov. 27, 1873) strontium; 4. cadmium; 5. lead; 6. cerium; 7. uranium.

Map of the Solar Spectrum.—Lockyer is engaged (*Proc. Roy. Soc.* xxiii. 152) in mapping the portion of the solar spectrum, together with the spectra of the metals, extending from w. l. 3900 to 4100, on a much larger scale than has hitherto been attempted, viz. nearly four times that of Angström's 'spectre normal.' This has been done by the aid of photography, and the spectra of the following elements have been photographed side by side with the solar spectrum, and the coincidences shown: Fe, Co, Ni, Mn, Ce, U, Cr, Ba, Sr, Ca, K, Al. The advantages of the photographic method over eye-observation may be estimated from the following comparisons of the number of lines obtained in the above region by different observers:

Number of lines in Angström's 'Spectre normal'	39
" " " and Thalen's map	185
" " Cornu's map	205
" " the New map	518

It will serve further to illustrate the advantages of this method if we compare the number of lines in the spectra of metals already observed with the number of lines of the same metal as given by Angström in his 'spectre normal':

Region 3900 to 4100.

Metal	New map	Angström's map and Thalen's
Fe	71	19
Mn	53	12
Co	47	—
Ni	17	—
Ce	163	—
U	18	—
Cr	24	—
Ba	7	—
Sr	5	—
Ca	7	6
K	2	—
Al	2	2
Total	416	39

Spectra of Chemical Compounds.—Lockyer (*ibid.* 1873, 285) has investigated the number and position of the true metallic lines seen when the electric spark is allowed to pass from various compounds of the given metal. The following lead salts were examined— PbF_2 , PbCl_2 , PbBr_2 , PbI_2 ; and it appears that the decrease in length and number of the metal lines observed in the case of the above salts follows the increase in the atomic weight of the non-metallic element, the lines dying out in the order of

their length. In other words, the greater the number of metallic lines which appear, the greater is the amount of dissociation going on. This was also found to hold good with the haloid compounds of the metals of the alkalis and alkaline earths.

Spectra of Mechanical Mixtures of Metals.—When an alloy of two or more metals is used as electrode, only certain of the lines of each metal are seen, and Lockyer (*loc. cit.*) has shown that the lines of the metal present in smallest quantity appear in least number, the shortest lines disappearing first as the percentage of metal is reduced, so that at last only one or two lines, and these the longest lines, remain.

Suggestions for a possible quantitative Spectrum Analysis.—By making use of the observations mentioned in the last paragraph the foundation of a quantitative-spectrum test is rendered possible (Lockyer, *Phil. Trans.* 1873, 261; 1873, 655; and 1874, 481; Lockyer & Roberts, *Proc. Roy. Soc.* 1873, 507). A series of experiments made with the gold-copper alloy used in coinage showed that it is possible, by carefully adjusting the striking distance of the spark, and by accurately observing the differences of length and breadth of certain lines seen in the spectrum of the alloy, to distinguish by spectrum observations differences in the composition of the alloy even smaller than those ascertainable by the ordinary assay. Thus, in the above alloy, $\frac{1000}{10000}$ increase in the gold made the lines shorter, and a similar increase in the copper made them longer.

Should it prove possible to ensure accuracy of observation and uniformity of condition, the practical importance of this branch of the inquiry can scarcely be overrated.

Photographing Spectra.—No process of mapping or drawing spectra of any kind can compete in accuracy and delicacy with photography. The photographs of the solar spectrum obtained, first by Rutherford and more recently by Draper (*Phil. Mag.* [4], xlv. 419), are models of accurate experimentation. Lockyer has applied this process to the delineation of the spark of the electric-arc-spectrum (*Phil. Trans.* 1874, 484, Bakerian lecture), a camera carrying a 5×5 -inch plate and a 3-inch lens of 23-in. focus replacing the observing telescope of the spectroscopic. The beam passing through the collimator and prisms was very small; the electric lamp was placed on its side so that the arc was horizontal, and thus the image of the short lines was projected on to the middle of the field, the longer ones extending beyond them on either side. The solar spectrum was used as a scale, an image of it being allowed to fall immediately adjacent to the metallic spectrum under examination. For this purpose a portion of the slit was covered up whilst the solar-spectrum passed through the free part. This portion was then closed by a shutter, and another portion opened for the metal-spectrum. In this way several metallic spectra may be photographed on a single plate, and the solar spectrum may be added for comparison. Of course maps of only those portions of the spectrum can thus be obtained in which the rays are capable of acting on the sensitive film; but, on the other hand, this method is capable of giving us information concerning the existence of lines in the ultra-violet portion of the spectrum which are invisible to the eye. Lockyer (*ibid.* 1874, 805) has constructed maps of the spectra of calcium, barium, and strontium from photographs taken by the method above described. The maps comprise the portion of the spectrum extending from wave-length 3900 to wave-length 4509.

On Lines coincident in different Spectra.—Lockyer (*loc. cit.* 511) has come to the conclusion that many of the cases hitherto supposed to be coincidences of lines in the spectra of two metals are due to the presence of traces of the one metal in the other. He bases his conclusions on the fact that most of these so-called coincidences, such as line 4607.5 of strontium, are found to be long in the spectrum of one metal and short in that of the other. Thus the above line is long in strontium, appears in calcium as a short line, and the coincidence is due, according to Lockyer, to the presence of a trace of strontium in the calcium. This is as a rule true in the case of those lines of iron, cobalt, chromium, and manganese, coincident with lines of calcium, which in the calcium-spectrum are long, but in that of the other metals are seen to be short. Hence, Lockyer concludes, we are justified in assuming that the short lines seen in the spectra of the above metals to be coincident with long and strong lines of calcium, are really due to traces of the latter metal occurring in the former as an impurity.

On the Spectrum of the Bessemer-Flame.—Recent observations made by Dr. W. Marshall Watts at the Barrow Hematite Iron and Steel Company's Works (*Phil. Mag.* [4], 45. p. 81, 1873), prove that the peculiar lines seen in the spectrum of the Bessemer flame are due to the presence of an oxide of manganese, and not, as was previously and on good ground supposed, to that of carbon. The results of these observations are given in a diagram which shows the spectrum on the scale of wave-lengths. With it are given upon the same scale the spectrum of iron, that of the flame obtained on adding the spiegel and that of oxide of manganese. A comparison of these drawings shows that the "spiegel-spectrum" is essentially the same as the Bessemer-spectrum, only further developed, and that the Bessemer-spectrum, whilst containing a few lines of

iron, sodium, and lithium, is essentially the spectrum of *oxide* of manganese. No lines certainly known to be produced by carbon have been observed. It has been repeatedly affirmed that the lines in the Bessemer-spectrum are due to metallic manganese, and this has been as frequently denied. The above experiments prove that no single coincidence is observed between the spark taken from manganese poles and the Bessemer-spectrum; but that if the spectrum of a manganese oxide is obtained by bringing pyrolusite, manganese chloride, or other manganese compound into the oxyhydrogen flame, the coincidence between the lines thus obtained and those of the Bessemer flame is so complete as to convince any one who sees them that the two spectra are identical. It is, however, singular that these bands should be seen with equal or nearly equal brightness when iron containing a mere trace of manganese is used as when a highly manganeseiferous iron is worked, and still more strange that this spectrum, which is not that of carbon, should disappear at the exact moment when all the carbon is burnt out. Possibly the point which it is necessary to hit is not that of the exact removal of the carbon, but that at which the injurious oxidation of the iron begins, and this takes place when the quantity of manganese becomes too small to combine with the excess of oxygen.

On the Carbon Spectrum.—W. M. Watts (*Phil. Mag.* [4], xlviii. 456) has shown that the so-called second spectrum of carbon, obtained by passing the induction spark through tubes containing carbonic oxide, carbonic acid, or olefiant gas, is in reality the spectrum of an oxide of carbon. For when the gases giving this spectrum are heated with metallic sodium, the spectrum changes to that known as the first carbon spectrum, whilst if oxygen be again introduced, the bands characteristic of the second carbon spectrum reappear.

On the Spectrum of the Aurora Borealis.—The late Professor Angström, to whom this branch of science owes so much, has recently shown that a spectrum containing at least three of the lines of the aurora (viz. 428.6, 470.3, and 522.6) can be obtained by passing an induction discharge through a partial air-vacuum over powdered phosphate of lime. A violet light thus obtained, similar to that which is usually seen only at the negative pole, fills the flask, and gives the following lines—427.2, 470.7, and 522.7. A red line about 630 and the bright yellow band are not thus obtained, and the only way in which Angström can account for this is that it probably owes its existence to phosphorescence or fluorescence. The spectrum of the aurora is composed, according to Angström, of two distinct spectra; one consisting of this homogeneous yellow light and the other of extremely feeble bands of light seen only in the strongest auroral displays. H. C. Vogel, who has also recently carefully examined the aurora-spectrum, has come to the conclusion that it is to be regarded as a modified air-spectrum.

A. S. Herschel (*Phil. Mag.* xlix. 65) gives an account of the aurora-spectrum. J. R. Capron (*ibid.* xlix. 249) has also made comparisons of other spectra with the spectrum of the aurora, as the results of which he concludes that much yet remains to be done before we can positively decide as to the exact nature of the aurora-spectrum.

Cometary Spectra.—Huggins has shown that observations on the spectra of five small comets examined in the years 1866, 1868, and 1871, led to the conclusion that a great part of the light of these comets was not reflected solar light, but light emitted by the matter of the comet, and that the coincidence existing between the three bright bands seen in the spectra of three of these comets and the bright lines of carbon compounds, seemed to indicate the presence of that body in some form in the cometary matter. Coggia's comet (visible in July 1874, *Proc. Roy. Soc.* xxiii. 154) is the first bright comet whose spectrum has been thus examined, and this exhibited three spectra, viz. :—

1. A spectrum of three bright bands similar in position and character to those seen in other comets, and these bands could be resolved into lines which were not exactly identical in position with the bright lines of carbon (spark in olefiant gas), all the cometary bands being shifted towards the blue. Supposing that the comet's bands are identical with those of carbon, the observed shift would indicate a relative motion of approach of comet and earth of about 40 miles a second, a velocity nearly double of their actual relative motion. Another point which renders the conclusion doubtful is that the lines of this comet are due to carbon is that the bright line near G, seen in all carbon spectra, was not observed in the spectrum of the comet.

2. A continuous spectrum of the nucleus in which no dark lines or bright lines, other than the above-mentioned three bands, could be seen.

3. A continuous spectrum which accompanies the gaseous spectrum in the coma, which represents almost entirely the light of the tail, and is partly due to reflected sunlight, as a portion of the light is polarized, and partly probably derived from the comet itself.

The difficulty which presents itself in accounting for sufficient heat to maintain this

matter and the nucleus in a state of incandescence has also to be encountered in respect of the gaseous matter, which emits the light and is resolved into bright bands.

Renvier (*Compt. rend.*) has shown that striped muscular fibre acts as a diffraction grating, and on this principle he has constructed a 'muscle spectroscope.'

SPINEL. Pseudomorphs of spinel after chlorite from the district of Slatoust in the Ural were found by v. Kokscharow a. Nikolajew (*Jahrb. f. Min.* 1870, 102) to contain

SiO ^a	Al ^a O ^a	FeO	MgO
2.96	68.96	18.01	10.82 = 100.75.

SPIRIT. The 'first runnings' of the distillate obtained in the manufacture of alcohol from sugar-beet, and from molasses, consist chiefly of aldehyde, together with paraldehyde and metaldehyde; they also contain crotonic aldehyde, and, according to Krämer a. Pinner, acetal (see ALDEHYDE, p. 32).

STAFFELITE. This calcic phosphate, occurring together with carbonate fluoride, &c., on phosphorite at Staffel, and in other localities (1st Suppl. 1037), is by some mineralogists regarded merely as an impure apatite (see *Jahresb. f. Chem.* 1870, 1317; 1871, 1172).

STANNIC COMPOUNDS. See TIN.

STARCH. On the structure of starch-grains, see Hartig (*Wien Akad. Ber.* [2ts. Abth.] lxiii, 805); *Jahresb. f. Chem.* 1871, 789).

On the size of starch-grains, see Schönn (*Dingl. pol. J.* cxv, 460; *Jahresb.* 1870, 1189); Hock (*ibid.* 1872, 1021). On the morphology of starch-grains: Hock (*Wiesner's Mikroskopische Untersuchungen*, pp. 55, 71; *Jahresb.* 1872, 1021).

Reactions: 1. With *Diastase.* According to Schulze a. Märker (*Dingl. pol. J.* cxi, 246), the ferment of malt-extract does not, like sulphuric acid, convert the whole of a given quantity of starch into sugar, but only the half of it. They conclude from their experiments that the action of diastase consists in the formation of a definite compound of sugar and dextrin, according to the equation:

O'Sullivan (*Chem. Soc. J.* [2], x, 581) finds that the ultimate product of the action of malt-extract on starch is maltose (v. 798), a sugar isomeric with milk-sugar, and capable, according to his observations, of reducing only two-thirds the quantity of cupric oxide that is reduced by dextroglucose (p. 766). By the prolonged action of acids, this sugar is completely converted into dextroglucose. On the action of malt-extract on starch, see also Schwarzer (*J. pr. Chem.* [2], i, 212; *Jahresb.* 1870, 854) and Contarot (*Compt. rend.* lxx, 282; *Jahresb.* 1870, 1195).

2. With *Acetic Anhydride.*—Starch-powder heated to 140° with about three times its weight of acetic anhydride containing 10 to 15 p.c. of acetic acid, swells up to a mass which, when washed with water, yields triacetyl-amidin, $C^6H^7(C^2H^3O)^3O$, a white powder, insoluble in water, alcohol, ether, and glacial acetic acid, not coloured blue by iodine, and reconverted by saponification into the original insoluble starch, which gives the blue reaction with iodine. If the mixture of starch and acetic anhydride is heated to 150°, a triacetyl-amidin is also formed, insoluble in water, alcohol, and ether, but differing from the former in being soluble in glacial acetic acid, and in yielding by saponification soluble starch. At higher temperatures a similar triacetyl-amidin is also formed, which, however, is converted by saponification into dextrin (Schützenberger, *Ann. Chim. Phys.* [4], xxi, 235).

3. With *Iodine.*—According to Duclaux (*Ann. Chim. Phys.* [4], xxv, 264; *Compt. rend.* lxxiv, 533) the formation of iodide of starch is a physical process, analogous to the absorption of lead-salts by charcoal. This conclusion is based on the following facts: a. The composition of iodide of starch is not constant. b. When iodine is added to an aqueous solution of starch, it does not act on the starch till the water has taken up a certain quantity of the iodine in the free state—that is to say, the iodine first dissolves in the water, then becomes divided between the water and the starch, and then only does the blue colour appear. c. The quantities of iodine which must be present in the water to produce the colour vary, under otherwise similar circumstances, with the temperature, and this explains the decoloration of iodide of starch by heat. d. The time at which the iodine begins to act upon the starch may often be accelerated or retarded by scarcely recognisable causes, in which no chemical action can be assigned.

c. The establishment of a state of equilibrium between iodine, starch and water depends upon the time, just like the absorption which is produced by charcoal.

The reactions of starch with iodine and with tannic acid have been examined by Griessmayer (*Ann. Ch. Pharm.* clx. 40; *Chem. Soc. J.* [2], x. 72), who finds that filtered starch-paste is in a state of continual change, being converted in about a week into a dextrin which gives a red colour with iodine, then in two or three days more into a dextrin which gives no coloration with iodine,—further into sugar, and finally into acid products. Tannic acid added in excess produces a precipitate as long as any unaltered starch is present, this precipitate disappearing on warming the liquid, and re-appearing on cooling.

On the reaction of starch with iodine in presence of dextrin, see O. Knab (*Chem. Centr.* 1872, 492, 508; *Jahresb.* 1872, 928).

4. With Aniline.—Starch heated with aniline is converted into dextrin (Schiff, *Deut. Chem. Ges. Ber.* iv. 908).

Animal Starch.—Granules exhibiting the physical and chemical characters of starch have been found by Daresto in the yolk of the hen's egg (*Compt. rend.* lxxii. 845; *Chem. Soc. J.* [2], lx. 838); also in the testicles, from which they disappear during the time of the formation of spermatozoa (*Compt. rend.* lxxiv. 131).

STARCH-SYRUP and STARCH-SUGAR. According to Krötke (*Dingl. pol. J.* cxix. 139), the addition of two ounces of strong nitric acid for every pound of sulphuric acid employed in converting starch into sugar, diminishes the time of boiling by one-half.

STASSFURTITE. See BORACITE (p. 206).

STILBENE or TOLUYLENE, $C^{14}H^{12} = C^6H^5-CH=CH-C^6H^5$. This hydrocarbon is found amongst the products of the dry distillation of Peru balsam (Kraut, *Arch. Pharm.* [2], cxli. 113).

It is formed in the decomposition of dibenzyl, $C^{14}H^{14}$, by heat (p. 177).

Stilbene crystallises in monoclinic forms, having the axial ratio:

Clino-diagonal	Ortho-diagonal	Principal axes
2.1561	1	1.8549.

Angle of inclined axes = $113^{\circ} 22'$.

Combination: $\infty P : \infty P\infty . 0P . P\infty . \frac{2}{3}P\infty$. Angle $\infty P : \infty P = 126^{\circ} 20'$; $\infty P : 0P = 100^{\circ} 23'$; $\infty P : P\infty = 101^{\circ} 42'$; $\infty P : \frac{2}{3}P\infty = 116^{\circ} 52'$; $0P : P\infty = 129^{\circ} 46'$; $\infty P\infty : \frac{2}{3}P\infty = 134^{\circ} 7'$; $\frac{2}{3}P\infty : \infty P = 108^{\circ} 31'$ (G. vom Rath, *Deut. Chem. Ges. Ber.* v. 622).

Stilbene, heated for some time to 150° – 160° with fuming hydrobromic acid, takes up bromine and hydrogen, forming a compound probably represented by the formula, $C^6H^5-CHBr-CH^2-C^6H^5$ (Zincke, *Deut. Chem. Ges. Ber.* v. 342).

Stilbene, oxidised by chromic acid, is converted into benzoic aldehyde and benzoic acid (p. 175).

STILBENE ALCOHOL. The name given by Limpricht a. Schwanert to Zinin's hydrobenzoin, $C^{14}H^{14}O^2$ (p. 172).

STIRLINGITE. This name is given by Konngott (*Jahrbuch f. Mineralogie*, 1872, 188) to a zinc chrysolite from Stirling Hill, Sussex County, New Jersey, analysed by W. T. Roepper (*ibid.* 1870, 392), and formerly regarded by him as tephroite. It occurs, with willemite, franklinite, jeffersonite, and spinel, in rhombic crystals two inches long, having the faces ∞P^2 , $P\infty$, $\infty P\infty$ predominant, and $2P\infty$, P , $2P^4$ (?) subordinated. Hardness = 5.5 to 6. Sp. gr. = 3.95 to 4.08. Dark green to black. Analyses 1 and 2 were made on carefully selected cleavage specimens; 3 on a massive variety:

	SiO ²	FeO	MnO	ZnO	MgO	X [*]	
1.	30.76	33.78	16.25	10.96	7.60	—	= 99.35
2a.	29.90	35.60	16.90	10.66	5.81	1.03	= 99.90
b.	30.68	35.44	16.93	10.70	5.44	1.04	= 100.11
3a.	30.67	35.37	17.81	9.87	5.69	1.39	= 100.80
b.	30.42	34.20	17.67	9.09	6.49	2.65	= 100.52

STRYCHNINE, $C^{21}H^{27}N^3O^2$. **Reactions:** 1. With Cyanides.—Potassium cyanide added to a strychnine solution throws down the pure base: strychnine does not, indeed, appear to form a hydrocyanide (Flückiger, *N. Jahrb. Pharm.* xxxviii. 138; Weith, *Deut. Chem. Ges. Ber.* iv. 527).

Insoluble residues (admixed spinel).

2. With *Chloracetic acid*.—On heating 3 pts. of finely powdered strychnine with 1 pt. of chloracetic acid to 180° for some hours, dissolving in water, and adding excess of ammonia, some unaltered strychnine separates, whilst the filtrate contains a new base, $C^{21}H^{22}N^2O^2$, which on evaporation is obtained in groups of white silky needles, readily soluble in hot water and alcohol, but not in ether. The solution has a neutral reaction. The formation of this compound is explained by the equations:

The nitrate and oxalate are very sparingly soluble in water. The solution of the base gives with potassium chromate a yellow crystalline precipitate, and with silver nitrate a silver compound crystallising in long colourless needles. It is also precipitated by bromine-water and tannic acid. With potassium chromate and sulphuric acid it gives the strychnine reaction. Subcutaneous injections of it produce tetanus in frogs. The constitution of this base and of its hydrochloride may be expressed as follows:

(F. Roemer, *Zeitschrift f. Chem.* 1871, 435).

3. With *Pernanganic acid*.—Wenzel (*Zeitschr. anal. Chem.* 1871, 226) recommends, as the most delicate test for strychnine, a solution of 1 pt. potassium permanganate in 2,000 pts. sulphuric acid, which produces a green colour, contrasting very strongly with the purple-red of the aqueous solution.

4. With *Cero-ceric oxide*.—See ALKALOIDS (p. 43).

5. On the separation of strychnine and *morphine*, see p. 818.

Periodides of Strychnine.—The following have been prepared by Jørgensen (*J. pr. Chem.* [2], iii. 145; compare 1st *Suppl.* 1039):

Strychnine tri-iodide, $C^{21}H^{22}N^2O^2.HI^3$	} Crystals of the rhombic system.
Methyl-strychnine tri-iodide, $C^{22}H^{23}N^2O^2.CH^3.I^3$	
Ethyl-strychnine tri-iodide, $C^{23}H^{25}N^2O^2.C^2H^5.I^3$	} Red-brown plates having an adamantine lustre. Sparingly soluble even in boiling alcohol.
Bromethylene-strychnine tri-iodide, $C^{21}H^{22}N^2O^2.C^2H^4Br.I^3$	
Amyl-strychnine tri-iodide, $C^{24}H^{28}N^2O^2.C^4H^9.I^3$	} Shining brown laminae, isomorphous with the ethyl-compound.
Amyl-strychnine pentioidide, $C^{24}H^{28}N^2O^2.C^4H^9.I^5$	
	} Nearly black prisms having an adamantine lustre.

Neither methyl-, ethyl-, nor bromethylene-strychnine, nor strychnine itself, appears to form a pentioidide.

Cobaltocyanide of Strychnine forms well-defined crystals having the composition $Co^2Cy^{12}(C^{21}H^{22}N^2O^2)H^4 + 8H^2O$. The *Nickelocyanide* has the composition $Ni^2Cy^{12}(C^{21}H^{22}N^2O^2)H^4 + 10H^2O$ (R. H. Lee, *Deut. Chem. Ges. Ber.* iv. 789).

Oxethyl-Strychnine, $C^{23}H^{25}N^2O^2 = C^{21}H^{22}(OO^2H^3)N^2O^2$. (R. Meissel, *Ann. Ch. Pharm.* clvii. 7). The *hydrochloride* of this base is formed by heating 10 grams of pulverised strychnine with 2.4 grams of the hydrochloride of ethylene-oxide, $C^2H^4O.HCl$, and alcohol in a sealed tube to 120° – 160° for about a day. On subsequently rinsing the tube with alcohol, expelling the alcohol by evaporation, and treating the residue with water, a small quantity of unaltered strychnine remains undissolved, while the easily soluble *oxethyl-strychnine hydrochloride*, $C^{23}H^{25}N^2O^2.HCl + H^2O$, separates from the concentrated solution in white silky needles. This salt has a sweet taste, with bitter after-taste; in a very dilute solution the sweet taste alone is perceptible. It exerts a strong paralyzing action on the motor nerves.

The solutions, even when very dilute, give with *platinic chloride* a crystalline double salt having a fine orange-red colour. *Potassium chromate* and *strong sulphuric acid* colour the aqueous solution violet, the colour disappearing after long standing. By boiling with *strong sulphuric acid*, the same reaction is obtained as with *strychnine*.

Dilute *nitric acid* forms with the solution of the hydrochloride, after addition of water, a yellow liquid which is turned red by stannous chloride. A strong solution of the chloride forms with *potassium sulphocyanate*, after 12 hours, large transparent crystals; with *potassium iodide*, long transparent needles.

Oxethyl-strychnine nitrate is obtained in hard, needle-shaped crystals, by precipitating the solution of the hydrochloride with silver nitrate. The *sulphate*, obtained by boiling the chloride with silver sulphate, forms large white crystals containing $(C_{28}H_{27}N_2O_3)SO_4 + 2H_2O$.

Oacetyl-Strychnine hydroxide, $C^{26}H^{42}N^2O^4$, is best prepared by precipitating the sulphate with a boiling saturated solution of baryta, removing the excess of baryta with a few bubbles of carbonic anhydride, evaporating, exhausting with alcohol, and precipitating the solution with ether. A small quantity of a brown amorphous body is then deposited, and adheres closely to the sides of the vessel, so that the nearly decolorised liquid can be decanted off clear, and, on further addition of ether, especially on agitation, the free base separates in small tufts of dazzling white crystals.

For the hydrochloride of oxethyl-strychnine, Messel suggests (from analogy with *pholine*) the structural formula:

STYPHENIC ACID. Syn. with TRINITRO-RESORCIN, see RESORCIN (p. 1043)*.

STYROL or **CINNAMENE**, $C^6H^5 - C^6H^5 = CH=CH^2$. When secondary ethyl-benzyl alcohol, $C^6H^5-CH(OH)-CH^3$ (obtained by treating a solution of acetophenone in dilute alcohol with sodium-amalgam) is heated for some time with zinc chloride in a vessel with reversed condenser, water is given up, and on subsequent distillation, a liquid passes over containing a large quantity of benzene, and yielding after repeated fractionation, a small quantity of a liquid which boils between 144° and 160° , and exhibits the properties of styrol from storax. Styrol appears also to be produced, and in larger quantity, by the action of alcoholic potash on chloroethylbenzene, $C^6H^5-CHCl-CH^3$ (Emmerling & Engler, *Deutsch. Chem. Ges. Ber.* iv. 147).

163). *Bromostyrols* or *Bromocinnamenes* (C. Glaser, *Ann. Ch. Pharm.* cliv.

163). *α*-Bromostyrol, $\text{C}_6\text{H}_5\text{—CH=CHBr}$, is formed from styrol dibromide, by heating with alcoholic potash; it is a yellowish, heavy oil, not volatile without decomposition, and having a sharp, tear-exciting odour. Heated to 120° with concentrated alcoholic potash, it yields acetenyl-benzene.

β -Bromostyrol, C^9H^7Br , is produced from phenyl-dibromopropionic acid (1st Suppl. 470) by heating with water; by the action of bromine on warm aqueous solutions of alkaline cinnamates; and by heating phenyl-bromolactic acid with water to 200°. It forms a light yellow oil, which boils without decomposition at 228°, and has a fine hyacinth odour. With nitric acid, it forms benzoic acid; it is not decomposed by alcoholic potash or potassium cyanide. (Glasgow, loc. cit.)— α -Chlorostyrol,

Chlorostyrols or *Chlorocinnamenes* (Glaser, *loc. cit.*)— α -Chlorostyrol, $\text{C}_6\text{H}_5\text{—CH=CHCl}$, is the compound obtained by Blyth & Hofmann (*Ann. Ch. Pharm.* liii. 292).— β -Chlorostyrol, $\text{C}_6\text{H}_5\text{—CCl=CH}_2$, is the compound which Stenhouse obtained by treating alkaline solutions of cinnamic acid with chlorine (*ibid.* lv. 3 and lvii. 70). Glaser obtained it as a bye-product in the preparation of phenyl-chlorolactic acid (*Jahresb. f. Chem.* 1867, 418); it may also be produced by heating phenyl-chloro-lactic acid with water to $200^\circ\text{--}220^\circ$. In the pure state it is a colourless oil, having an agreeable odour of hyacinth, boiling at 199° under a pressure of 766 mm. and at 119° under a pressure of 40 mm. Sp. gr. = 1.112 at 22.3° . By oxidation, it yields benzoic acid. On heating it with alcoholic potash and with potassium cyanide to $200^\circ\text{--}250^\circ$, partial resinisation takes place, but no chloride of potassium is formed.

SUBERIC ACID, $C_8H_{14}O_4$. This acid, heated to 160° with the required quantities of bromine, is converted into monobromosuberic acid, $C_8H_{13}BrO_4$, and dibromosuberic acid, $C_8H_{12}Br_2O_4$; and these acids, boiled with potash and treated with alcohol, yield suberomalic acid, $C_8H_{12}O_6$, and suberotartronic acid, $C_8H_{10}O_6$, both uncrystallisable and forming salts which crystallise with difficulty (H. Gal. & J. Gay-Lussac, *Compt. rend.*, lxx. 1175).

SUCCINIC ACID, $C^4H^4O^4 = C^4H^4(COOH)^2$. *Alleged occurrence in Urine.*—The statement of Meissner a. Joly (v. 453), that succinic acid is found in the urine of dogs fed on flesh and fat, is contradicted by E. Salkowski (*Pfuger's Archiv. f. Physiologie*, iv. 21), who obtained no indication of its presence in the urine of a dog fed for a month on a copious diet of flesh and fat, although the detection of it is easy. His experiments likewise indicate that this acid does not occur in human urine.

Formation.—Wippermann (*Deut. Chem. Ges. Ber.* iii. 337) has obtained succinic acid, together with other products, by the action of ethylic dibromacetate on the mixture of sodacetic ethers which Frankland a. Duppa obtained by the water of sodium on ethyl acetate.

Succinates.—According to Béchamp (*Compt. rend.* lxx. 909), calcium succinate fermented in contact with microzyme chalk (1st Suppl. 614) and a small quantity of meat, yields not a trace of hydrogen, but only propionic and carbonic acids:

According to Lutschak (*Deut. Chem. Ges. Ber.* v. 30), zinc succinate is capable of uniting with 3 mols. ammonia, forming the compound $C^4H^4ZnO^2.3NH^3$.

SUCCINIC AMIDES AND ANILIDES. (Menschutkin, *Ann. Ch. Pharm.* cxlii. 165, 187).

Succinimide, $C^4H^4O^2.NH$ = $C^4H^4 \begin{matrix} \diagup CO \\ \diagdown CO \end{matrix} NH$, is obtained in satisfactory

quantity by distilling ammonium succinate as quickly as possible. It boils at 237° – 288° , leaving a small residue of charcoal. The hydrogen of succinimide is replaceable only by silver or mercury. *Argento-succinimide*, $C^4H^4O^2.NAg$, has been already described (v. 461). In the hydrated compound, $2(C^4H^4O^2.NAg) + H^2O$, the water does not appear to exist as water of crystallisation.

Mercurio-succinimide, $(C^4H^4O^2.N)^2Hg$, formed on dissolving mercuric oxide in a hot aqueous solution of succinimide, is moderately soluble in alcohol, extremely soluble in cold water, and crystallises therefrom in long needles having a silky lustre.

On adding solution of mercuric chloride to an aqueous solution of mercurio-succinimide, a precipitate is formed, consisting of microscopic, shining, rhombic tables, less soluble in water than mercurio-succinimide itself, and represented by the formula $(C^4H^4O^2.N)^2Hg.HgCl$.

Succinamide, $C^4H^4O^2(NH^2)^2$, is formed by the action of alcoholic ammonia on succinimide even at ordinary temperatures, but more quickly by heating the materials together to 100° in a sealed tube for several hours.

Mercurio-succinamide, $C^4H^4O^2(NH^2)^2.HgO + \frac{1}{2}H^2O$, is formed on dissolving recently prepared mercuric oxide in a boiling aqueous solution of succinamide, and separates on cooling as a white powder.

Succinamates.—The ammonium salt remains in the alcoholic mother-liquor of succinamide obtained as just described, when the alcohol used contains water. The calcium salt, $(C^4H^4NO^2)^2Ca$, is formed by boiling succinamide with milk of lime, and separates on passing carbonic anhydride into the filtrate, evaporating over the water-bath, and adding alcohol, as a pulverulent crystalline precipitate, or in stellate groups of short prisms; from dilute solutions in long needles.

Succinanil or Phenylsuccinimide may be conveniently prepared by pouring aniline (1 mol.) on succinic acid (1 mol.) in a retort, heating gradually, and as soon as the boiling ceases, distilling the succinanil over at a stronger heat. It may be purified by recrystallisation from water or alcohol; and by dissolving it in strong sulphuric acid, precipitating with water and recrystallising from alcohol, it may be obtained perfectly colourless, in needles, or in long, thin, strongly refracting prisms. It melts at 166° , is nearly insoluble in cold, sparingly soluble in boiling water, more easily in boiling alcohol; boils above 300° without decomposition.

Succinanilic or Phenylsuccinamic acid.—The barium salt of this acid, $(C^6H^5NO^2)^2Ba + 3H^2O$, is obtained by dissolving succinanil in boiling baryta-water, removing the excess of baryta by carbonic acid, and concentrating, in suits of crystalline needles having a satiny lustre, easily soluble in water, and giving off their water of crystallisation at 110° . The calcium salt, $(C^6H^5NO^2)^2Ca + 4H^2O$, and the lead salt, prepared in like manner, crystallise in needles. The silver salt, $C^6H^5NO^2Ag$, is obtained by double decomposition, as a precipitate, which quickly becomes crystalline, dissolves with difficulty in boiling water, and crystallises therefrom in anhydrous prismatic crystals. Free succinanilic acid, $C^6H^5O^2(C^6H^5NH)OH$, is obtained by precipitating the calcium salt with hydrochloric acid, and recrystallising the precipitate

from boiling water, in small concentrically grouped needles, which are nearly insoluble in cold water, but dissolve easily in alcohol and in boiling water. The acid melts at 148.5° , and is resolved at a higher temperature into water and succinil. It does not give off aniline when treated with aqueous potash.

Phenylsuccinamides.—*Monophenylsuccinamide*, $C^6H_5O^2\{NH^2\}NHC^6H_5$, is formed, together with a small quantity of ammonium succinilate, by heating succinil with alcoholic ammonia. It crystallises from water in broad needles, dissolves with moderate facility in hot water, sparingly in alcohol, melts at 181° , and forms a very sparingly soluble compound with mercuric oxide. Quicklime converts it into succinilic acid.

Diphenylsuccinamide or *Succinilide*, $C^{12}H^{10}O^2(NHC^6H_5)^2$, is obtained as a by-product in the preparation of succinil. The portion insoluble in water may be crystallised from alcohol, then boiled with alcoholic potash, and purified by recrystallisation. It crystallises from alcohol in broad, flat, shining needles, which melt at 226.5° to 227° . It is very stable, dissolves in nitric and sulphuric acids, and is precipitated therefrom by water without alteration. When heated to 100° in a sealed tube with strong hydrochloric acid, it is resolved into aniline and succinic acid, and when distilled, it splits up into aniline and succinil.

SUCCINIC CHLORIDE, $COCl-CH^2-CH^2-COCl$. This compound, mixed with acetic acid, and treated with sodium-amalgam, is converted into a butylene glycol, which appears to be the true homologue of ethylene glycol:

SUCCINYLBENZAMIC ACIDS. By fusing succinic acid with amidobenzoic acid, two acids are obtained, namely, succinylbenzamic acid, $C^{11}H^7\{N(C^6H^4O^2)^2\}COOH$, which is soluble in water, and melts at 235° , and succinyldibenzamic acid, $C^{12}H^8O^2(NH.C^6H^4O^2)^2$, which is insoluble in water. The former is an imidogen acid, and is converted, by fixation of water, into oxysuccinylbenzamic acid, $C^{11}H^7\{NH.C^6H^4O^2.OH\}COOH$. The second acid is also produced by heating the first with amidobenzoic acid (Muretow, *Deut. Chem. Ges. Ber.* v. 330).

SUCCINYLBENZOLIN, $(C^{11}H^{11}O^2)^2.C^6H^5O^2$, is formed by the action of succinic chloride on benzoin. It crystallises from alcohol in shining leaflets; is insoluble in water, but soluble in alcohol ether and carbon sulphide; melts at 129° ; and is converted by alcoholic potash into benzilic and succinic acids (A. Lukanin, *Deut. Chem. Ges. Ber.* v. 331).

SUCCINYLBENZOLIN-SULPHAMIDE, $N^2H^2(C^6H^4SO^2)^2(C^6H^5O^2)$. See **TOLUENE-SULPHAMIDES** (p. 1168).

SUGARS. 1. *Reaction with Chlorine and Water.*—Hlasiwetz & Barth, in 1861, by treating milk-sugar with bromine and water, obtained a brominated compound which, when decomposed by bases, yielded isodiglycolethyleneic acid, $C^6H^{10}O^4$ (iii. 414, 1023). The same treatment has more recently been applied by Hlasiwetz & Habermann (*Ann. Ch. Pharm.* clv. 120) to other kinds of sugar. The results show that the capability of a sugar to form such an acid containing the same number of carbon-atoms in itself, increases with the fermentability of the sugar, non-fermentable or difficultly fermentable sugars being converted by this process into acids containing smaller numbers of carbon-atoms.

Moderately dilute solutions of sugars were treated with chlorine gas, as long as it continued to be absorbed, the action in the case of rather large quantities going on for four or five days. The liquid was then freed from chlorine by drawing air through it, warmed in a dish, and a magma of silver oxide added to it till the liquid became neutral. It was then filtered, the undissolved matter washed for a long time with neutral water; the filtrates, which generally began to grow brown and turbid from reduced silver, were immediately treated with hydrogen sulphide; and the mostly limpid acid liquids filtered from the silver sulphide were concentrated on the water-bath. From the crude acids thus obtained, mostly containing more or less undecomposed sugar, the calcium salts were prepared, and from these, through the medium of the lead salts, the free acids were obtained.

Cane-sugar and dextroglucose yield gluconic acid, $C^6H^{12}O^7$ (p. 550), differing by H^2O from lactonic or isodiglycolethyleneic acid from milk-sugar. Levulose and by H^2O from lactonic or isodiglycolethyleneic acid from milk-sugar. Lævulose and by H^2O from lactonic or isodiglycolethyleneic acid from milk-sugar. Disaccharin yield glycollic acid. Phloroglucin yields dichloroacetic acid. Diac-

garding the intermediate products, and reducing the process to its simplest expression, the four following cases are to be distinguished:

The chlorine or bromine in these reactions appears to be simply added on to the sugar-molecule, and the acid to be formed by substitution of O for Cl² or Br² in the chlorinated or brominated compound thus produced, e. g.:

These sugars behave then like unsaturated compounds, as indeed Linnemann has shown to be the case with dextroglucose, which by taking up H² is converted into mannite (iii. 823).

2. *Action of Nascent Hydrogen.*—Bouchardat (*Compt. rend.* lxxiii. 199, 1008) has shown that cane-sugar, glucose, and milk-sugar are converted by the action of sodium-amalgam in presence of water into mannite or dulcite, and a certain number of monatomic alcohols, viz., ethyl alcohol, isopropyl alcohol, and a hexyl alcohol identical with that which Erlenmeyer and Wanklyn obtained from mannite and dulcite. Dextroglucose treated in this manner yields the three volatile alcohols just mentioned, together with mannite; milk-sugar the same volatile products, together with dulcite; inverted milk-sugar a mixture of mannite and dulcite.

3. *Reactions with Acetic Anhydride.*—The products obtained by the action of acetic anhydride on glucose and cane-sugar, according to the latest investigations of Schützenberger (*Ann. Ch. Pharm.* [4], xxi. 235) differ in some respects from those described in the *First Supplement* (p. 1045).

1. Pure crystallised dextroglucose dried at 100° is easily attacked by acetic anhydride at 120°, the products differing according to the proportions used. One part of glucose and 2½ pts. of anhydride heated in an open vessel react readily, the action being over in a few moments; a little water being added to destroy the anhydride, and the whole evaporated to dryness on the water-bath an amorphous residue soluble in water, and of a very bitter taste, is obtained. Boiling benzene only partly dissolves this residue, the soluble part being triacetyl-glucose, C⁶H⁷(C²H³O)³O⁶. This body, heated to 140° by itself or with acetic anhydride, loses water, giving triacetyl-glucosan, C⁶H⁷(C²H³O)³O⁵, insoluble in water, soluble in dilute acetic acid. The insoluble part dissolved in water, and decolorised by animal charcoal, yields, on evaporation in a vacuum, an amorphous, light yellow, bitter mass, very soluble in water, and soluble in alcohol; this is diacetyl-glucose, C⁶H⁹(C²H³O)²O⁶.

Glucose, heated with a large excess of anhydride to 160° for 6 hours, does not form a glucose-derivative, but one derived from two molecules of glucose, which coalesce with loss of H²O, according to the equation:

All the eight hydrogen-atoms of the hydroxyl present in this diglucose may be replaced by acetyl, forming C¹²H¹⁰O¹¹, which is either identical or isomeric with the compounds of the same composition obtained by the action of acetic anhydride on cane- and milk-sugars; in water it is insoluble, in alcohol soluble; it has no marked taste of any kind.

All the acetylated derivatives of glucose are dextrorotatory.

2. Cane-sugar heated with ½ pt. acetic anhydride, and 3-4 pts. glacial acid, entirely

* The old formula of milk-sugar is used in this equation merely to show more clearly the analogy of the reaction to that which takes place in the other cases. With the new formula, the equation would be: C¹²H²²O¹¹ + O = H²O + C¹²H²⁰O¹⁰.

dissolves; other throws down a yellow tarry precipitate, which, when dried in a vacuum over quicklime, and finally at 100°, is a solid substance soluble in water and alcohol, of a faint sweet taste, somewhat inclined to bitter, insoluble in ether and benzene; this is monoacetyl-saccharose, $C^{12}H^{21}(C^2H^3O)O^{11}$. The ethereal filtrate from this substance evaporated to dryness, dissolved in water, and decolourised by animal charcoal, gives numbers intermediate between those required for tetra- and penta-acetyl-saccharose, and is probably a mixture of these two bodies; it is soluble in water, alcohol, and ether.

Heated with a large excess of acetic anhydride, cane-sugar yields hepta- and octo-acetyl-saccharose, $C^{12}H^{13}(C^2H^3O)^7O^{11}$ and $C^{12}H^{14}(C^2H^3O)^8O^{11}$, as gummy amorphous bodies insoluble in water, and much resembling the octoacetyl-diglucose obtained with glucose.

3. *Milk-sugar* is less easily acted on than cane-sugar; after long boiling, however, in an open vessel it dissolves completely. From the product water precipitates octo-acetyl-lactose, $C^{12}H^{14}(C^2H^3O)^8O^{11}$; the solution contains tetra-acetyl-lactose, which forms indistinctly shaped crystals of a bitter taste; these bodies have the rotatory powers $[\alpha] = +31^\circ$, and $[\alpha] = +50.1^\circ$ respectively.

On the Acetyl-derivatives of Mannite, see MANNITH (p. 774).

Estimation of Sugars.—1. Estimation and separation of Cane-sugar, Invert-sugar and Dextroglucose or Grape-sugar. The following method is given by J. Apjohn (*Chem. News*, xxi. 86; *Zeitschr. anal. Chem.* ix. 498). The amount of cane-sugar is first determined by the optical method, and then, after inversion, the sum of the three sugars. If then x denote the cane-sugar, y the grape-sugar, and z the invert-sugar, 0.24, 0.086, and 0.182 being the rotations produced in the polarising apparatus by 1 gram of cane-sugar, grape-sugar, and invert-sugar respectively, 1.16 the ratio between the half-molecular weight of the cane-sugar and that of the grape-sugar, and 1.1 that between the molecular weight of the invert-sugar and the grape-sugar, we have the equations:

$$\begin{aligned} 0.24x - 0.086y + 0.182z &= t \\ 1.16x + 1.1y + z &= w, \end{aligned}$$

from which the magnitudes y and z can be calculated.

Instead of determining the amount of cane-sugar by the optical method, which is difficult, as the syrup always acquires a more or less dark colour by inversion, the determination may be made by the chemical method. For this purpose it is merely necessary to test the syrup with copper-solution before and after inversion, the difference of the two determinations giving the amount of cane-sugar. The equations to be used are:

$$1.1y + z = w,$$

where w is the quantity of grape-sugar corresponding with y and z ; after inversion:

$$1.16x + 1.1y + z = w,$$

where w is the quantity of grape-sugar corresponding with x , y , and z . Therefore:

$$x = \frac{w - w'}{1.16}.$$

The numbers obtained, according to these equations, from direct experiments, did not give perfectly accordant results. The discrepancy is attributed by Apjohn to the presence in the syrup of a substance different from the three kinds of sugar, but nevertheless capable of producing circular polarisation, and perhaps also of reducing copper solution, e.g. dextrin, asparagin, &c.

A. Dupré (*Chem. News*, xxi. 97; *Zeitschr. anal. Chem.* ix. 501) likewise estimates the three kinds of sugar above mentioned by a combination of the optical and chemical methods, which he regards as more direct than that of Apjohn. Cane-sugar does not reduce copper solution, and is not altered by heating it in solution with caustic alkalis, whereas grape- and fruit-sugar are completely destroyed. The cane-sugar may, therefore, be estimated by polarisation after the other kinds of sugar have been destroyed, and the other two sugars may be determined together by the chemical method, independently of the presence or absence of cane-sugar. It only remains, therefore, to determine the rotation produced by all the three sugars together, and we shall then have all the data required for the calculation. In a Jellet's instrument it was found that 1 p.c. cane-sugar required for compensation 0.2418 inch of levogyrate turpentine; 1 p.c. fruit-sugar required 1.502 inch of a 10 p.c. solution of cane-sugar; and 1 p.c. grape-sugar required 0.836 inch of the same solution of cane-sugar. If, then, x denotes the required quantity of fruit-sugar, y that of the grape-sugar, p the sum of

the two in percentages, as given by the copper-solution, a the number of inches of a 10 p.c. solution of cane-sugar which, according to observation, is required to compensate the mixture p , of fruit- and grape-sugar, or is equivalent thereto, we have the equations:

$$x + y = p$$

$$1.502x - 0.836y = \pm a$$

therefore,

$$x = \frac{0.836p + a}{2.338}$$

$$y = p - x.$$

The + sign is used for a when the mixture of the two sugars relates to the left; the - sign when the same mixture rotates to the right. Dupré has applied this method only to the estimation of sugar in wine, but he considers that it will be likewise applicable to cane-sugar and syrups.

Cane-sugar or Saccharose. On the specific heat of cane-sugar solutions, see Hnat (p. 601).

Solubility in mixtures of Alcohol and Water.—O. Scheibler (*Deut. Chem. Ges. Ber.* 1343) has investigated the solubility of cane-sugar in aqueous alcohol of different strengths and at different temperatures. Mixtures comparatively poor in alcohol dissolve more sugar than the water contained in them would dissolve by itself, but the more highly alcoholic mixtures the reverse is the case. The proportion in which alcohol neither promotes nor hinders the solution of sugar in water, is 46 p.c. by volume at 40°, and 50 p.c. at 14°. An aqueous solution of sugar saturated at 65°

tains 66 p.c. sugar; at 40°, 75½ p.c.; and at 14°, 66 p.c. The last-mentioned solution, when mixed with an equal volume of absolute alcohol, will still remain saturated at that temperature, but a further addition of alcohol causes the separation of sugar. Sugar is but very slightly soluble in alcohol of more than 90 p.c., and quite insoluble in absolute alcohol.

For the tabulated results, see the original paper.

Action of Light.—A solution of 10 grams of white cane-sugar in 50 grams of water enclosed in a sealed tube, from which the air had been expelled by boiling the liquid, and kept for five months exposed to light, was found to be about half converted into glucose. A similar solution kept for the same time in the dark remained unaltered (Raoult, *Compt. rend.* lxxiii. 1049).

For Maumené's experiments on the action of water and heat, or of heat alone, upon cane-sugar, see *Bull. Soc. Chim.* [2], xvii. 442.

Distillation with Lime.—Frémy, by distilling sugar with quicklime, obtained a distillate consisting chiefly of metacetone, $C^6H^{10}O$ (iii. 932). R. Benedikt (*Ann. Ch. Pharm.* cxlii. 303), by distilling 1 pt. of sugar with 3 pts. of lime, as recommended by Gottlieb (*ibid.* lii. 127), obtains a distillate consisting of a watery and an oily layer. The watery layer contains acetone, together with a small quantity of acetic acid. The oily layer contains metacetone, boiling at 83°–84° (isomeric with mesityl oxide, b.p. 181°), and isophorone, $C^9H^{14}O$, boiling at 210°, yielding, when treated with phosphoric anhydride, a hydrocarbon having approximately the composition $C^{12}H^{12}$, but not identical with camene or with mesitylene.

Metacetone and phorone are the chief liquid products of the distillation of sugar with lime; they occur, however, only in small quantity in comparison with the gaseous products, which consist mainly of hydrocarbons. Benedikt gives, as a probable representation of the decomposition of sugar by lime, the equation:

and regards the metacetone and phorone as products of condensation of the acetone formed in the first instance:

The higher-boiling portions of the crude distillate probably contain still higher condensation-products of the same kind.

Oxidation by Potassium Permanganate.—Maumené (*Compt. rend.* lxxv. 85) finds that when a solution of 200 grams of permanganate, dissolved in 4 litres of water, is poured into a solution of 200 grams of sugar-candy in 2 litres of water, the mixture in fifteen to twenty minutes becomes heated to 45°–48°, manganic oxide separates in a lump, and a colourless neutral solution is formed, no longer sweet, but retaining its optical rotatory power unaltered. In this liquid Maumené, on the strength of a few qualitative reactions, assumes the existence of two acids, which he designates as *hexepinic* and *tricipinic* acids.

Combinations.—1. With Alkali salts (C. H. Gill, *Chem. Soc. J.* [2], ix. 269). Peligot described a compound of cane-sugar with sodium chloride having the composition $C^{12}H^{22}O^{11}.NaCl$ (v. 473). Blondran de Carrolas described a similar compound containing $2C^{12}H^{22}O^{11}.2NaCl.3H^2O$. Mitscherlich, and afterwards Hochstetter and several other chemists, denied the existence of any saline compounds of cane-sugar. Gill, on the other hand, by leaving a sugar-solution, boiled with excess of common salt, to stand for several months, obtained a few small crystals having the composition $2C^{12}H^{22}O^{11}.3NaCl.4H^2O$. A number of similar experiments were made with solutions containing a double molecule of sugar to 1, 2, 3, or 4 mols. of a chloride, bromide, or iodide of an alkali metal.

The potassium salts did not yield compounds of definite composition; some of them, indeed, yielded well-defined crystals containing sugar and salt, but always in variable proportion.

Of the compounds with sodium chloride, that which was obtained from the mixture containing the smallest proportion of salt was to all appearances identical with that described by Peligot. It crystallised from the mixture containing 2 mols. salt to 2 mols. sugar. The crystals, which are prisms with pyramidal summits, do not deliquesce easily, give off all their water of crystallisation when dried for several hours at a temperature of 60° to 70°, and crystallise anhydrous from a solution of 85 p.c. spirit. When a solution in 75 p.c. spirit is mixed with ether, an oily layer separates at the bottom, in which crystals form and continue to grow for 8 to 10 months. These crystals are identical with those of the original compound recrystallised from water, and have the composition $C^{12}H^{22}O^{11}.NaCl.2H^2O$. The two other solutions containing

sodium chloride, also gave salts of the same composition. The crystals accidentally obtained at the beginning of the investigation were never reproduced.

Mauméné (*Compt. rend.* lxxii. 508) has obtained the compound of sugar with sodium chloride in fine rhombic prisms containing 18.3 p.c. NaCl; it was found by special experiments to contain unmodified cane-sugar.

Sugar solutions, containing *sodium bromide*, gave with difficulty a few crystals, the composition of which, $C^{12}H^{22}O^{11}.NaBr.1\frac{1}{2}H^2O$, seemed to indicate the presence of impurities (Gill).

Sodium iodide and cane-sugar form extremely fine monoclinic crystals, the same compound, $2C^{12}H^{22}O^{11}.3NaI.3H^2O$, being always obtained in whatever proportions its components may be mixed, and crystallising without alteration any number of times from water or aqueous alcohol. In the aqueous solutions the rotatory power of the sugar is unimpaired by the presence of the sodium iodide. The crystals are monoclinic, and have their optic axes in a plane perpendicular to the plane of symmetry (Gill).

Lithium chloride, bromide, and iodide do not form definite compounds with cane-sugar. The corresponding *ammonium salts* form very deliquescent crystals containing variable quantities of ammonia. Acetate, nitrate, and phosphate of sodium do not appear to combine with cane-sugar (Gill).

From the composition of the compound with sodium iodide Gill infers that the true molecular weight of cane-sugar is represented by the formula $C^{12}H^{44}O^{22}$.

With Lime. According to Horsin-Déon (*Bull. Soc. Chim.* [2], xvii. 155) tribasic sucrate of lime, treated with alcohol, yields the sexbasic sucrate, just as the monobasic sucrate, similarly treated, yields the bibasic compound (v. 473). The mono- and tri-calcic sucrares contain constitutional water; the bi- and sexcalcic compounds do not. The two latter are therefore formed by corresponding reactions:

The compound of sugar, lime, and carbonic anhydride, called 'hydrosucro-carbonate of lime,' exhibits, according to Horsin-Déon (*Bull. Soc. Chim.* [2], xv. 22), the following properties: a composition varying with the particular lime sucrate used in its preparation and with the temperature; solubility in sugar-water in presence of lime; decomposition into sucrate and carbonate of lime by sugar-water; capability of formation at all temperatures of experiment and at all densities of the liquid employed. Its varying composition is shown by the following experimental results:

Solution of Lime Sucrate employed	Weight of CO ² absorbed to 28 pts. by weight of Lime	Experimenter
6 eq. Lime + 1 eq. Sugar	11 parts	Boivin a. Loiseau
5 " " 4 " "	4.4 "	Horsin-Déon
5 " " 3 " "	13.2? "	"
3 " " 2 " "	16.28 "	"
1 " " 1 " "	15.90 "	Dubrunfant
1 " " 1 " "	14.70 "	Horsin-Déon

Milk-sugar or Lactose, $C^{12}H^{22}O^{11}$, or $C^{12}H^{44}O^{22}$. *Oxidation*.—According to Laubenheimer (*Ann. Ch. Pharm.* clxiv. 283), milk-sugar, mixed in aqueous solution with a small quantity of soda, is oxidised by potassium permanganate at ordinary temperatures slowly, but at the boiling heat very quickly and almost completely, to carbon dioxide and water. Attempts to convert it by partial oxidation into malic or isomalic acid were unsuccessful; the filtrate separated after the reaction from manganese dioxide, containing nothing but oxalic acid and uncrystallisable acids.

Action of Aniline.—Milk-sugar, heated with twice its weight of aniline, yields, according to circumstances which have not yet been clearly made out, either two nitrogenous products, or only one. The formation of these bodies may be represented by the equations:

Both these bodies are very soluble in water, very sparingly soluble in absolute alcohol, nearly insoluble in pure ether. They reduce alkaline cupric solutions. Bromine, added to their aqueous solutions, disappears immediately (*W. Sächse, Diss. Chem. Ges. Ber.* iv. 834).

Glucose (dextro) or Dextrose, Lævulose, and Invert-Sugar, $C_6H_{12}O_6$. *Action of Haloids and of certain Chlorides on Dextrose.*—Chlorine does not act on anhydrous dextrose at ordinary temperatures, but at 80° a greenish coloration is produced, and at 112° the mass swells up and becomes carbonised. Bromine acts in a similar manner, but the sealed glass tubes in which the action takes place always break at 80° . Iodine does not act on dextrose either at 80° or in sunshine. In a stream of hydrogen chloride, at 70° , dextrose turns brown, and is converted into a dry black powder.

Acetyl chloride acts on dextrose at ordinary temperatures, producing aceto-chlorohydrate, $C^6H^7(C^2H^3O)^4ClO^3$, together with acetic and hydrochloric acids (p. 12).

By the action of chlorine and water, dextrose is converted into gluconic acid, $C^6H^{12}O^7$ (p. 559).

When dextrose is heated with *baryta-water*, a precipitate is formed; consisting of the barium salt of saccharumic acid, $C^{12}H^{18}O^{11}$ (p. 1063), and the liquid filtered therefrom contains the barium salt of glucic or glucinic acid (p. 556).

Lævulose treated with chlorine and water yields glycollic acid (p. 1104).

Invert-sugar treated with water and sodium-amalgam is partly converted into mannito (p. 773).

The action of the electric current on invert-sugar has been examined by H. T. Brown (*Chem. Soc. J.* [2], x, 578). Twenty-four hours after the commencement of the experiment the evolved gas was found to have the following percentage composition :

Carbon dioxide	14.15	Hydrogen	72.80
Carbon monoxide	3.34	Oxygen	9.71

The distillate neutralised with sodium carbonate exhibited the reactions of aldehyde, and the residue in the retort, on further distillation with a little sulphuric acid, yielded a large quantity of acetic and a small quantity of formic acid. The formation of alcohol could not be distinctly proved, but Brown regards it as probable, from the composition of the electrolytic gases. Brister (*Archives Néerlandaises*, 1866, i. 296; *Jahresb.* 1866, 87) obtained, by the electrolysis of a solution of cane-sugar, carbon dioxide and an acid distillate possessing reducing properties, but in which he could not detect either acetic or formic acid.

Saccharine Substance from Lime-leaves. A viscous saccharine liquid adhering to the upper side of the diseased leaves of a lime-tree was found by Boussingault (*Ann. Chim. Phys.* [4], xxv. 5) to consist of 55.44 p.c. cane-sugar, 24.75 invert-sugar, and 19.81 dextrin, which is nearly the composition of manna from Sinai (55 cane-sugar, 25 invert-sugar, and 20 dextrin). It melted when exposed to the sun, and fell in drops to the ground, but resumed its viscous state in the shade. Saccharine matter was also found in the healthy leaves of the same tree, but in much smaller quantity, and it was free from dextrin.

On **Bornesite**, see p. 206; **Dambonite**, p. 421; **Dulcite**, p. 440; **Inosite**, p. 669; **Mannite**, p. 773.

Synanthrose, $C^{12}H^{22}O^{11}$ (O. Popp, *Ann. Ch. Pharm.* clvi. 181). This is a variety of sugar which always accompanies inulin in the tuber-bearing Compositae or Synanthroae; it occurs in all stages of growth, but most abundantly in the ripe bulbs. *Dahlia variabilis* yields it in the greatest quantity and purest state; but the tubers of the Jerusalem artichoke (*Hedysanthus tuberosus*) may be advantageously used for its preparation. The freshly-expressed juice is treated with lead acetate; the excess of lead removed by sulphuric acid; the filtrate neutralised with magnesium carbonate, again filtered, and evaporated to the consistence of an extract; the residue re-again filtered, and evaporated to the consistence of a solution possesses rotatory power; the peatedly exhausted with alcohol so long as the solution possesses rotatory power; the solution evaporated; and the residue exhausted with small quantities of alcohol (not absolute). The resulting solution is treated with animal charcoal, and poured in a thin stream into a mixture of absolute alcohol and ether, and the bulky, white, amorphous precipitate is quickly filtered off, washed with a mixture of alcohol and ether, and dried in a vacuum.

Synanthrose is isomeric with cane-sugar; deliquescent; easily soluble in water and dilute alcohol; difficultly soluble in absolute alcohol, insoluble in ether; optically inactive; does not reduce the solution of copper, or does so only after it has become altered by boiling. Dilute acids convert it into dextrose and levulose. The rotatory power of inverted synanthrose is $\alpha = -54.09^\circ$, and is not influenced by temperature. Its flavour is faint, but not sweet. It is not directly fermentable; yeast acts upon it indeed, but only after splitting it into dextrose and levulose. At 140° - 145° it turns brown, evolves gas, and passes into caramel, glucose and levulose, the latter apparently optically inactive. Cold caustic alkalis do not turn it brown. Cold concentrated sulphuric acid produces less colour with it than with cane-sugar. Silver

1110 SULPHALDEHYDE—SULPHAZOTISED ACIDS.

nitrate in the cold gives a white precipitate, which is reduced on heating, and partially on drying. Copper salts and mercuric chloride give no precipitate, mercuric nitrate gives a bulky white precipitate without reduction. Mercurous nitrate and Millon's solution are at once reduced by it in the cold. Neutral and basic lead acetate give no precipitate; lime and baryta-water give precipitates only on addition of alcohol. Synanthrose does not combine with sodium chloride or other neutral salts; it is decomposed by chlorine and hypochlorites, and gives by dry distillation carbon oxide and dioxide, marsh-gas, acetic acid, and acetone. It forms a hydrate, $C^{12}H^{22}O^{11} + H^2O$, the water in which cannot be driven off in the air-bath without decomposition of the synanthrose; it appears to form a similar compound with alcohol. The barium compound, $C^{12}H^{18}O^{11}Ba^2$, easily decomposed by carbon dioxide, is difficultly soluble in water, insoluble in alcohol, and easily soluble in dilute acids. The lead compound, $C^{12}H^{18}O^{11}Pb^2$, is more stable than the barium compound, and dissolves easily in acetic acid or lead acetate.

Synanthrose interferes with the precipitation of copper, iron, and chromium oxides. Ferric oxide, freshly precipitated in the cold, dissolves in solution of synanthrose, and by evaporation is reduced to magnetic oxide, glucose being also formed. By treatment with chromic acid or lead dioxide, it yields formic acid. With hot dilute nitric acid, it gives saccharic and oxalic acids.

When synanthrose is treated with a cold mixture of 1 pt. concentrated nitric acid and 2-2½ pts. sulphuric acid, an explosive nitro-compound is formed, soluble in alcohol, less soluble in water than synanthrose itself. By acetic, butyric, and tartaric acids at 100°, synanthrose is converted into glucose. The prolonged action of sulphuric or hydrochloric acid produces glucic acid and finally humus compounds.

SULPHALDEHYDE. See ALDEHYDE (p. 37).

SULPHAMIDOBENZOIC ACIDS. See SULPHOBENZOIC ACIDS (p. 1113).

SULPHAMMONIC ACIDS. See SULPHAZOTISED ACIDS (*infra*).

SULPHANILIC ACID, $C^6H^5NSO^3 = C^6H^4 \begin{Bmatrix} NH^2 \\ SO^3H \end{Bmatrix}$. This acid, formed from aniline and sulphuric acid, is converted by nitrous acid into diazosulphanilic acid, $C^6H^4 \begin{Bmatrix} N=N \\ SO^3H \end{Bmatrix}$, which, when heated with water, yields a phenol-sulphonic acid, $C^6H^4 \begin{Bmatrix} OH \\ SO^3H \end{Bmatrix}$, convertible by fusion with potash into resorcin. The same diazosulphanilic acid, heated with hydrobromic acid, yields a bromo-benzenesulphonic acid, $C^6H^4 \begin{Bmatrix} Br \\ SO^3H \end{Bmatrix}$, also convertible by fusion with potash into pure resorcin. According to the view now entertained of the composition of resorcin, these facts indicate that the sulphanilic acid prepared by direct combination is a meta-compound (1 : 3). On the other hand, when the bromobenzenesulphonic acid obtained as just described, is distilled with potash, it yields dicyanobenzene, $C^6H^4(ON)^2$, which, by boiling with potash, is converted into terephthalic acid, which is a para-compound. Hence, it appears probable that the conversion of the bromobenzenesulphonic acid into dicyanobenzene is accompanied by a molecular transposition (see BENZENE, p. 136).

SULPHAZOTISED ACIDS. (Claus, *Deut. Chem. Ges. Ber.* iv. 186, 221 and 504; *Ann. Ch. Pharm.* clviii. 52, 104; *Bull. Soc. Chim.* [2], xv. 179; xvi. 76; *Chem. Soc. J.* [2], ix. 307, 659). These acids, of which the sulphammonic acids (1st Suppl. 1047) form a particular group, are produced by the action of sulphurous acid on potassium nitrite. Their formation depends on a simple reduction of the nitrous acid, but with this peculiarity, that before the reduction has proceeded so far as the formation of ammonia, the more or less reduced product from the nitrous acid enters into combination with the group SO^3K , resulting from oxidation of the sulphurous acid. Thus the sulphoxazic acids are the stepping stones to the sulphammonic acids, the former being, in fact, convertible into the latter by further reduction with sulphurous acid. The formation of the sulphazotised acids is, however, partly assisted by the tendency of trivalent nitrogen to pass into the quinquivalent condition. Just as potassium nitrite can pass into nitrate by taking up an atom of oxygen, so likewise has it a tendency to take up the bivalent group SO^3 :

The compound SO^3NO^2K , which, in the ordinary method of preparing these acids (p. 1111), is decomposed as fast as it forms, may, in fact, be isolated by acting on potas-

sium nitrite with an alcoholic solution of sulphurous acid, the salt so formed, immediately separating out and being thereby withdrawn from the further action of the sulphurous acid. On again subjecting this salt to the action of sulphurous acid, which, perhaps, takes place according to the equation :

other sulphazotised acids are produced by the action of the nascent hydrogen, either on the newly formed salt, or on the compound which precedes it, or finally on the potassium nitrite, with or without the simultaneous action of fresh sulphurous acid.

The usual mode of preparing the sulphazotised acids is to pass sulphurous acid into an alkaline solution of potassium nitrite, the products thus formed varying in composition accordingly as the solution is cooled or not during the passage of the gas.

All these acids are sulphonic acids, containing either trivalent or quinquivalent nitrogen, which may also be united with oxygen or with hydrogen. Claus accordingly distinguishes three groups :

1. *Sulphammonic compounds*, all containing quinquivalent nitrogen, which, besides the sulphonic group $\text{SO}^{\cdot}\text{K}$, is combined only with hydrogen. These compounds, when ignited with soda-lime, give off the whole of their nitrogen as ammonia.

2. *Sulphoxyazic compounds*, likewise containing only quinquivalent nitrogen, which, however, is united with oxygen as well as with hydrogen. When heated with soda-lime, they give off only a part of their nitrogen in the form of ammonia.

3. *Sulphamic compounds* containing only trivalent nitrogen.

Of these three classes, the following compounds have been examined :

(1). Sulphammonates :

$\text{N}^{\cdot}\text{H}(\text{SO}^{\cdot}\text{K})^4$ Tetrasulphammonate of potassium

$\text{N}^{\cdot}\text{H}^2(\text{SO}^{\cdot}\text{K})^3$ Trisulphammonate of potassium

$\text{N}^{\cdot}\text{H}^3(\text{SO}^{\cdot}\text{K})^2$ Disulphammonate of potassium.

The monosulphammonate, $\text{N}^{\cdot}\text{H}^4(\text{SO}^{\cdot}\text{K})$, has not been obtained; it would be isomeric, or perhaps even identical, with ammonio-potassic sulphite, $\text{SO} \begin{Bmatrix} \text{OK} \\ \text{ONH}^4 \end{Bmatrix}$.

(2). Sulphoxyazates :

$\text{ON}^{\cdot}\text{H}(\text{SO}^{\cdot}\text{K})^2$. Disulphoxyazate of potassium: hard, transparent, shining crystals sparingly soluble in cold, easily in hot water; decomposes when heated above 60° .

$\text{ON}^{\cdot}(\text{SO}^{\cdot}\text{K})^3$. Trisulphoxyazate of potassium: shining, transparent, rhombic plates, moderately stable.

$\text{HN}^{\cdot} - \text{N}^{\cdot}\text{O}$
 $\begin{array}{c} ||| \quad | \\ (\text{SO}^{\cdot}\text{K})^3\text{OK} \quad | \\ | \quad | \end{array}$
 $(\text{SO}^{\cdot}\text{K})^3\text{OK}(\text{SO}^{\cdot}\text{K})$. Sulphazotate of potassium: colourless, translucent, rhombic plates, which may be heated to 150° .

$\text{N} - \text{NO}$
 $\begin{array}{c} \diagup \quad \diagdown \\ | \quad | \\ (\text{SO}^{\cdot}\text{K})^3 \quad | \\ | \quad | \end{array}$
 $(\text{SO}^{\cdot}\text{K})^3(\text{SO}^{\cdot}\text{K})$. Oxy-sulphazotate of potassium: needles of a deep yellow colour; very unstable.

(3). Sulphamates :

$\text{NH}(\text{OH})(\text{SO}^{\cdot}\text{K})$. Sulphhydroxylamate of potassium.

$\text{NH}(\text{OH})(\text{SO}^{\cdot}\text{H})$. Sulphhydroxylamic acid.

The aqueous solution of this acid may be boiled for a short time without decomposition.

Instead of the names above given to the compounds of the first and second groups, the following, in which the prefix 'azo' denotes nothing more than a nitrogen-compound, are proposed by Michaelis (*Jahresb. f. Chem.* 1872, 234), as more characteristic:—

$\text{NH}(\text{SO}^{\cdot}\text{K})^4$	Hydrazotetrasulphonate
$\text{NH}^2(\text{SO}^{\cdot}\text{K})^3$	Hydrazotrisulphonate, &c. &c.
$\text{ONH}(\text{SO}^{\cdot}\text{K})^3$	Hydrazoxydisulphonate
$\text{ON}(\text{SO}^{\cdot}\text{K})^4$	Azotetrasulphonate
$\text{N}^{\cdot}\text{HO}^{\cdot}\text{K}(\text{SO}^{\cdot}\text{K})^4$	Diazohydroxypotassiotetrasulphonate
$\text{N}^{\cdot}\text{O}^{\cdot}(\text{SO}^{\cdot}\text{K})^4$	Diazotetrasulphonate.

SULPHETHERS OF ETHYLENE. See ETHYLENE (p. 491).

SULPHIDES OF HYDROGEN. *Monosulphide: Sulphydric acid: Sulphuretted Hydrogen.*—On the formation and preparation of this gas, and the decomposition of its aqueous solution, see p. 661. The gas is commonly said to require a red heat to decompose it. According to J. Myers, however (*Ann. Ch. Pharm.* cliz. 124), the decomposition begins at 400°, and proceeds rapidly at the boiling point of sulphur.

Basicity of Sulphydric acid.—J. Thomsen (*Pogg. Ann.* cxxxix. 193; *Jahresb.* 1870, 120) regards sulphydric acid as a monobasic acid, H.SH ; first, because the heat developed on adding to it successive quantities of sodium hydrate does not increase after the addition of 1 mol. NaHO (1st *Suppl.* 683); secondly, because the second atom of hydrogen cannot be replaced by sodium acting on the aqueous solution. For similar reasons also he regards water as a monobasic acid, H.OH . According to this view, the so-called neutral sulphides, such as Na^2S —like the corresponding anhydrous oxides, *e. g.*, Na^2O —cannot exist in aqueous solution, and the soluble normal salts of sulphydric acid must be regarded as Na.SH , $\text{Ba}(\text{SH})^2$, $\text{Mg}(\text{SH})^2$, &c. Kolbe (*J. pr. Chem.* [2], iv. 412) objects to this view, on the ground that, if an aqueous solution of sodium sulphide contains nothing but the sulphydrate and hydrate of sodium, it should, when treated with potassium ethylsulphate, yield nothing but mercaptan, whereas it always yields in addition ethyl sulphide, $(\text{C}^2\text{H}^5)^2\text{S}$, the quantity of which is greater as the solution of sodium sulphide is more concentrated. Kolbe therefore concludes that the resolution of the sodium sulphide into sulphydrate and hydrate is complete only in very dilute solutions (such as those used by Thomsen), and very partial in concentrated solutions, and therefore that Thomsen's view of the monobasicity of sulphydric acid is erroneous. Thomsen (*ibid.* v. 247) agrees with Kolbe that the decomposition of metallic sulphides by water is more complete in dilute than in concentrated solutions, but regards his inference from the formation of ethyl sulphide in the reaction just mentioned as inconclusive, inasmuch as the reaction is complicated by the presence of sodium hydrate.

Persulphide.—The composition of this compound is still a matter of doubt. Hofmann, in 1868, obtained a crystalline compound of hydrogen persulphide with strychnine, having the composition $\text{C}^{21}\text{H}^{22}\text{N}^2\text{O}^2.\text{H}^2\text{S}^2$, and hence inferred that the persulphide itself is H^2S^2 ; he did not, however, succeed in isolating it. Similar results have recently been obtained by W. Ramsay (*Chem. Soc. J.* [2], xii. 857), who likewise did not succeed in isolating the persulphide, or in obtaining it of definite composition by any other process. Drochsel (*J. pr. Chem.* [2], iv. 20; *Jahresb.* 1871, 211), on the other hand, regards the persulphide as a pentasulphide, H^2S^5 , analogous to K^2S^5 , because it may be formed from the latter (?) by decomposition with acids), and reconverted into it by the action of alcoholic potassium sulphydrate:

Hydrogen persulphide is an almost colourless oil of sp. gr. 1.7342, somewhat soluble in alcohol, insoluble in benzene and chloroform. It dissolves phosphorus and iodine, but the solutions gradually decompose, giving off sulphydric acid, and forming phosphorus iodide or hydriodic acid respectively. Chlorine passed through it forms hydrochloric acid and sulphur chloride, S^2Cl^2 . Bromine acts in a similar manner. *Sulphurous anhydride* has but very little action on it. *Ammonia*, either gaseous or in solution, decomposes it instantly, leaving sulphur in a peculiarly brittle blistered state. On *organic bodies* the persulphide exerts a more powerful reducing action than the monosulphide (Ramsay).

SULPHIDES, METALLIC. *Formation by the action of Alkaline Sulphides on Metals* (Priwosnik, *Ann. Ch. Pharm.* clxiv. 46).—Pure copper immersed in yellow ammonium sulphide to which a considerable quantity of sulphur has been added, becomes covered with a crust of cupric sulphide, CuS , blue-black on the outer, brown-black on the inner surface, easily separating from the metal and continually renewed. If the action be allowed to go on for several days, the monosulphide changes into black cuprous sulphide, Cu^2S , the supernatant transparent and colourless liquid then consisting of ammonium monosulphide. The yellow solutions of potassium and sodium sulphide likewise give up their excess of sulphur to copper, and become colourless. This reaction affords an easy method of forming the alkaline monosulphides; a little copper, however, is apt to be taken up. *Sodium thiosulphate* is also decomposed at the boiling heat by copper, especially in the finely divided state; thus:

Silver, as is well known, is blackened by alkaline sulphides. Chemically pure silver immersed in yellow ammonium sulphide becomes coated with a very closely adhering lead-gray film, which becomes thicker on prolonged immersion, and after about six

weeks forms a crystalline crust of the monosulphide Ag_2S , which easily splits off on bending the plate.

Tin, under similar circumstances, likewise unites with sulphur, but does not form a crust, because the resulting sulphide dissolves in the sulphide of alkali-metal.

Nickel behaves exactly like tin, imparting to yellow ammonium sulphide a dark colour which passes through brown into black. This reaction serves to distinguish nickel from cobalt (p. 849).

An *iron wire*, a millimeter thick, immersed in ammonium polysulphide, gradually became covered with an extremely thin velvet-black film, which was easily rubbed off.

Formation by the action of Thiosulphates.—Metallic oxides or salts, heated with anhydrous sodium thiosulphate, are converted into sulphides, exhibiting, for the most part, the same colours as when they are formed by precipitation with hydrogen sulphide. Manganic oxide, however, is converted into green oxysulphide, Mn^2OS , and stannic oxide into brown stannous sulphide (Landauer, *Zeitschr. Ann. Chem.* 1872, 427).

Action of Iodine on Insoluble Sulphides.—A mixture of zinc sulphide and dry iodine immediately becomes hot, with separation of sulphur, and formation of zinc iodide; to complete the decomposition, however, the mixture must be heated to 200° in sealed tubes. Zinc sulphide suspended in water is acted on in the same manner by iodine, either dry, or dissolved in water or alcohol, excepting that a small quantity of zinc sulphate (15 pts. to 1000 of the zinc sulphide) is produced at the same time. The sulphate is also formed in small quantity, together with zinc iodide and free sulphur, in the action of dry zinc sulphide on solutions of iodine in ether or chloroform; no sulphate, however, is formed in the action of zinc sulphide on iodine dissolved in carbon sulphide. Native *zinc blende* is attacked by iodine only at high temperatures, best at 200° ; in presence of water a little sulphate is likewise formed. The formation of the sulphate appears to be due, not to the absorption of oxygen from the air by the sulphide, but to the decomposition of water, with formation of hydriodic acid. Similar results are obtained by the action of iodine on the sulphides of manganese, cadmium, iron, nickel, cobalt, tin, antimony, arsenic, bismuth, lead, mercury, silver, and platinum (Filhol a. Mellies, *Ann. Chim. Phys.* [4], xxii. 58).

On the electric conductivity and electromotive power of metallic sulphides, see ELECTRICITY (p. 446); also *Chem. News*. xxiii. 161.

SULPHINIC ACIDS. Organic sulphur-acids formed on the type $\text{R}-\text{SOOH}$, R denoting a monatomic alcohol radicle; they contain 1 at. oxygen less than the sulphonic acids.

SULPHOBENZENIC or SULPHOBENZOLIC ACIDS. Syn. with BENZENESULPHONIC ACIDS (p. 152).

SULPHOBENZOIC ACID, $\text{C}_6\text{H}_5\text{O}_2\text{SO} = \text{C}_6\text{H}_5 \begin{Bmatrix} \text{SO}^+\text{H} \\ \text{COOH} \end{Bmatrix}$. **Formation.**—Benzoyl chloride, treated with sulphuric acid, is converted into benzoyl-sulphuric acid, $\text{SO}_2 \begin{Bmatrix} \text{OH} \\ \text{O}(\text{C}_6\text{H}_5\text{O}) \end{Bmatrix}$, which on keeping, and still more on heating, changes into the isomeric sulphobenzoic acid, identical with that which is prepared by the action of sulphuric acid on benzoic acid (Oppenheim, *Deut. Chem. Ges. Ber.* iii. 735).

Action of Potassium Hydrate.—Crude sulphobenzoic acid fused with potash is converted into a mixture of oxybenzoic and paraoxybenzoic acids. These two acids cannot be separated by fractional crystallisation; but an approximate separation may be effected by adding barium hydrate to the mixed solution of their barium salts, whereby a basic barium paraoxybenzoate is formed, which is but slightly soluble in water; oxybenzoic acid does not form a basic barium salt under these circumstances. The formation of these two acids shows that crude sulphobenzoic acid is a mixture of meta- and parasulphobenzoic acid.

Acid Parasulphobenzate of Barium, $(\text{C}_6\text{H}_5\text{SO})_2\text{Ba} + 3\text{H}_2\text{O}$, is sparingly soluble in hot water (much less than the meta-salt), nearly insoluble in cold water; when pure it crystallises from the hot solution in flat needles, which fill the containing vessel from top to bottom. The neutral potassium salt is very easily soluble both in hot and in cold water, and crystallises in needles. When fused with potash it yields perfectly pure paraoxybenzoic acid, whereas the potassium salt prepared from acid metasulphobenzate of barium yields by fusion with potash nothing but oxybenzoic acid (Ira Remsen, *Zeitschr. f. Chem.* [2], vii. 81, 199).

Amidosulphobenzic Acids, $\text{C}_6\text{H}_4(\text{NH}_2)\text{O}_2\text{SO}^+\text{H}$ (Griess, *J. pr. Chem.* [2], v. 244). Two isomeric acids having this composition are obtained by heating a solution of amidobenzoic acid in fuming sulphuric acid to 170° , dissolving the resulting dirty-white crystalline mass in a large quantity of boiling water, neutralising with barium

carbonate, and evaporating the solution to the crystallising point. It then deposits small, well-defined, six-sided tables or prisms consisting of the barium salt of one of the sulpho-acids, and the mother-liquor, on further evaporation, yields thick white needles or small prisms of the barium salt of the other acid. This last-mentioned barium salt has the composition $C^6H^4(NH^2)O^2.SO^2Ba + 3H^2O$. On supersaturating its hot aqueous solution with hydrochloric acid, the free acid separates almost completely on cooling, in soft, white, six-sided laminae, or in nodules, very slightly soluble in boiling water, almost insoluble in alcohol and ether. It is anhydrous, has a sour taste, and is bibasic. Heated with strong nitric acid it is converted, with separation of sulphuric acid, into an easily soluble nitro-acid.

The barium salt of the other amidosulphobenzoic acid has, when air-dried, the composition $C^6H^4(NH^2)O^2.SO^2Ba + 2H^2O$. By converting it into an ammonium salt and precipitating the solution of the latter with hydrochloric acid, the free acid is obtained in narrow four-sided laminae, which are easily soluble in hot water, and have, when air-dried, the composition $C^6H^4(NH^2)O^2.SO^2H + H^2O$.

These amidated sulpho-acids are likewise produced, with separation of carbon dioxide and ammonia, by the action of fuming sulphuric acid on amidobenzoic cyanide (1st Suppl. 317). The amidosulphobenzoic acid, which Limpriecht and v. Usler obtained by reducing nitrosulphobenzoic acid with ammonium sulphide (v. 488), is probably a third modification.

Bromosulphobenzoic Acid, $C^6H^3BrSO^2 = C^6H^3Br \begin{Bmatrix} CO^2H \\ SO^2H \end{Bmatrix}$ (Roeters van Lennep, *Zeitschr. f. Chem.* [2], vii. 67). This acid is prepared by heating bromobenzoic acid (m. p. 152°) with sulphuric anhydride till the mixture nearly ceases to give off vapour of the anhydride, then pouring it into water, separating the solution from unaltered bromobenzoic acid, boiling the filtrate with lead carbonate, and decomposing the resulting lead salt with hydrogen sulphide. It crystallises in small, delicate, deliquescent needles. Its salts, especially the neutral salts, crystallise very badly, forming dense masses which retain moisture, so that it is difficult to determine their amount of water of crystallisation. The *neutral sodium salt* forms clusters of small needles. The *acid sodium salt*, $C^6H^3Br.CO^2H.SO^2Na$, separates from the solution of the neutral salt in hydrochloric acid, and may be obtained in well-defined needles by recrystallisation from alcohol. The *neutral barium salt*, $C^6H^3Br.CO^2.SO^2Ba + 2\frac{1}{2}H^2O$, crystallises in tufts of needles easily soluble in water and in rather strong boiling alcohol. The *acid barium salt*, $(C^6H^3Br.CO^2H.SO^2)^2Ba + H^2O$, is formed when the neutral salt is crystallised from hydrochloric acid, and may be obtained in very small needles by recrystallisation from alcohol. The *calcium salt*, $C^6H^3Br.CO^2.SO^2Ca + 1\frac{1}{2}H^2O$, obtained by boiling the crude acid with slaked lime or chalk, dissolves easily in water, sparingly in alcohol either cold or hot, and crystallises easily from hot alcohol in needles. The *magnesium salt* forms small needles easily soluble in water, sparingly in alcohol. The *copper salt*, $C^6H^3Br.CO^2.SO^2Cu$, forms nodular groups of green, sparingly soluble needles. The *lead salt*, prepared as above described, also forms nodular groups of needles sparingly soluble in water and in alcohol. The *silver salt*, $C^6H^3Br.CO^2Ag.SO^2Ag$, crystallises in white, slightly soluble needles.

Action of Phosphorus Pentabromide on Sodium Bromosulphobenzoate.—This reaction, which probably takes place according to the equation:

yielded an oil, which was washed with water to remove sodium bromide, and then boiled with water to convert the group COBr into the group COOH. Heat partly decomposed the resinous product, thus:

It was now dissolved in soda-solution, filtered from the insoluble portion, and precipitated by hydrochloric acid, when it yielded a very small quantity of an acid. Neither this acid, nor its sodium salt, could be obtained in a distinctly crystalline state from their solutions in alcohol or water, but one or two sublimations gave the acid in slender glistening needles melting at 182°–184°.

Thiobenzoic Acid, $C^6H^4 \begin{Bmatrix} SH \\ COOH \end{Bmatrix}$ (Hübner a. Upmann, *Zeitschr. f. Chem.* [2], vi. 291; van Leunep, *loc. cit.*) This acid, the sulphur-analogue of oxybenzoic acid, is prepared: 1. By heating sodium sulphobenzoate with twice its weight of phosphorus pentachloride, and treating the resulting sulphobenzoic chloride, $C^6H^4.SO^2Cl.COCl$, with tin and hydrochloric acid. The crystalline mass which separates is washed with hydrochloric acid, dissolved in ammonia, precipitated by an acid,

SULPHOCAMPHORIC ACID—SULPHOCARBAMIDE. 1115

and recrystallised from alcohol containing hydrochloric acid (Hübner a. Upmann). 2. By reducing bromothiohydrobenzoic acid (*infra*) with sodium-amalgam and water, precipitating with dilute sulphuric acid and recrystallising from water (van Lennep).

Thiohydrobenzoic acid is nearly insoluble in water, sparingly soluble in alcohol, and crystallises from the latter in needles having a faint yellowish colour, but may be obtained white by solution in ammonia and precipitation by hydrochloric acid. It melts at 242° – 244° . The ammonium salt, $C^6H^4(SH)CO^2NH^4 + H^2O$, is soluble in water and alcohol, and separates, on evaporation, as a granulo-crystalline mass. The barium salt, $[C^6H^4(SH)CO^2]^2Ba + 2\frac{1}{2}H^2O$, is obtained by precipitating a boiling, very dilute solution of the ammonium salt with barium chloride, in small white prismatic needles. The calcium salt, $[C^6H^4(SH)CO^2]^2Ca + 3H^2O$, is a light yellow granulo-crystalline precipitate. The zinc and lead salts are likewise obtained by precipitation (Hübner a. Upmann).

Bromothiohydrobenzoic acid, $C^6H^4Br \begin{Bmatrix} SH \\ CO^2H \end{Bmatrix}$, is prepared from bromosulphobenzoic acid in the same manner as thiohydrobenzoic acid from sulphobenzoic acid. The mass, separated by the action of tin and hydrochloric acid, dissolves for the most part in alcohol, and, on evaporating the solution, the bromothiohydrobenzoic acid separates in small colourless needles melting at 256° (Upmann), at 242° – 243° (van Lennep). It is insoluble in water, but dissolves easily in alcohol. By the action of water and sodium-amalgam it is converted into thiohydrobenzoic acid. The zinc salt, $(C^6H^4Br.SHCOO)^2Zn$, is precipitated on adding zinc sulphate to a solution of the ammonium salt; it is insoluble in water. The lead salt, $(C^6H^4Br.SHCOO)^2Pb$, is a white precipitate, insoluble in water, prepared by adding lead acetate to a solution of the ammonium salt. The barium salt, $(C^6H^4Br.SHCOO)^2Ba$, forms a white precipitate, obtained by adding barium chloride to the ammonium salt. It is somewhat soluble in boiling water, and, on evaporation, separates in microscopic crystals. The calcium salt, like the barium salt, is a white precipitate. The sodium salt, after treatment with iodine, yields an acid having a melting point of 130° . Its lead and zinc salts, $(C^6H^4Br.S.CO^2)^2Zn$, are white precipitates, insoluble in water (van Lennep).

SULPHOCAMPHORIC ACID, $C^6H^{10}SO^4$. This acid and its salts are inactive to polarised light, although they are derived from the anhydride of camphoric acid, which has a rotatory power of about -7° (Kachler, *Ann. Ch. Pharm.* clxii. 259).

SULPHOCARBAMIDE. Sulphurea, $CS \begin{Bmatrix} NH^2 \\ NH^2 \end{Bmatrix}$.—This body, heated in a sealed vessel with nearly anhydrous aldehyde, forms the compound $CS \begin{Bmatrix} N.C^2H^4 \\ NH^2 \end{Bmatrix}$, which dissolves sparingly in ether and cold alcohol, more readily in hot alcohol, not at all in cold water, and is decomposed, by boiling with water, into aldehyde, sulphocarbamide, and a small quantity of ammonium sulphocyanate. Dilute acids act upon it in the same way (J. E. Reynolds, *Chem. News*, xxiv. 87).

The analogous oxygen-compound, $CO \begin{Bmatrix} N.C^2H^4 \\ NH^2 \end{Bmatrix}$, described by Schiff (*Ann. Ch. Pharm.* cli. 206), is formed by the action of aldehyde on carbamide (urea).

Diphenylsulphocarbamide, $N^2(CS)(C^6H^5)^2H^2$.—On the action of an alcoholic solution of nitrous ether on this compound, see p. 436.

Oxybenzoylsulphocarbamide, $C^6H^4N^2O^2S = N^2 \begin{Bmatrix} CS \\ C^6H^4O^2 \\ H^2 \end{Bmatrix}$.—This compound is formed by heating amidobenzoic sulphate on the water-bath with a quantity of water not sufficient to dissolve it completely, and adding an equivalent quantity of potassium sulphocyanate in crystals, whereupon the whole dissolves in the form of easily soluble amidobenzoic sulphocyanate, $C^6H^4NO^2.CHNS$. By very strong concentration a crystalline deposit is obtained, consisting chiefly of potassium sulphate; and, on evaporating to dryness on the water-bath, exhausting with alcohol, evaporating the alcoholic solution to dryness, and crystallising the residue several times from boiling water, oxybenzoylsulphocarbamide, resulting from molecular transformation of the amidobenzoic sulphocyanate, is obtained in the pure state.

Oxybenzoylsulphocarbamide is nearly insoluble in cold water and alcohol, but dissolves readily in both these liquids at the boiling heat. The hot aqueous solution forms white precipitates with the chlorides of barium and calcium and the nitrates of silver and lead, and a brown-red precipitate with ferric chloride. It is desulphurised by silver or lead nitrate in presence of alkalis, also by mercuric oxide and silver oxide, being probably converted into the carbamide of oxybenzoic acid (Arzruni, *Deut. Chem. Ges. Ber.* iv. 406).

Pseudotolyl-sulphocarbamide, $C^6H^4N^2S = CS(NH.C^6H^3)$, is formed by heating pseudotoluidine on the water-bath, with an alcoholic solution of carbon sulphide, as long as hydrogen sulphide continues to escape, and separates out, partly during the reaction, partly on cooling. This compound, when recrystallised from alcohol, forms white woolly needles extremely soluble in alcohol and ether, melting at 165° (uncorr.) (E. Gerard, *Deut. Chem. Ges. Ber.* iv. 985).

SULPHOCARBIMIDES. See SULPHOCYANIC ETHERS (p. 1117).

SULPHOCARBONYL CHLORIDE, $CSOCl^2$. See CARBON SULPHOCHLORIDES (p. 266).

SULPHOCINNAMIC ACID, $C^6H^5SO^2$. Cinnamic acid treated with strong sulphuric acid yields two isomeric sulpho-acids. The para-acid, $C^6H^5SO^2 + 5H^2O$, crystallises in large monoclinic prisms; its barium salt, $(C^6H^5SO^2)^2Ba + 3H^2O$, forms long, sparingly soluble needles. By fusion with potash the acid is converted into paraoxybenzoic acid. The isomeric acid forms indistinct crystals; its barium salt, $(C^6H^5SO^2)^2Ba + 1\frac{1}{2}H^2O$, crystallises in nodules. The salts of this latter acid are more soluble than the corresponding para-salts. By fusion with potash it appears to yield oxybenzoic acid.

SULPHOCOUMARILIC ACID, $C^6H^4O^2SO^2$ (Perkin, *Chem. Soc. J.* [2], ix. 49). This acid is formed by digesting 1 pt. of coumarin with 5 pts. of fuming sulphuric acid on the water-bath for an hour or two. The product dissolves perfectly in water, and the solution neutralised with barium carbonate yields, besides barium sulphate, the soluble barium salt of sulphocoumarilic acid; and by decomposing this salt with the exact quantity of sulphuric acid required, then filtering, and evaporating, first over the water-bath, afterwards in a vacuum, sulphocoumarilic acid is obtained in easily soluble needles having the composition $C^6H^4O^2SO^2H + 2H^2O$. The ammonium salt crystallises in silky, easily soluble needles. The sodium salt forms transparent rhombic crystals nearly insoluble in alcohol. The potassium salt crystallises in flat prisms. The barium salt, $(C^6H^4O^2SO^2)^2Ba + 5H^2O$, and the strontium salt, $(C^6H^4O^2SO^2)^2Sr + H^2O$, crystallise well.

Disulphocoumarilic Acid, $C^6H^4O^2(SO^2H)^2$. A mixture of about 8 pts. fuming sulphuric acid and 1 pt. coumarin, heated to 150° – 160° , for an hour or two, yields a product containing sulphocoumarilic and disulphocoumarilic acids; and on neutralising this mixture with barium carbonate, evaporating to dryness, and treating the residue with warm water, barium sulphocoumarilate is dissolved, while the less soluble disulphocoumarilate remains behind, and may be purified by recrystallisation from warm water. This salt, $C^6H^4O^2(SO^2)^2Ba + H^2O$, forms a white crystalline powder nearly insoluble in cold, and but slightly soluble in hot water (Perkin).

SULPHOCYANACRINYL or ACRINYL SULPHOCYANATE, C^6H^4NSO . A product of the decomposition of sinalbin. See MUSTARD (p. 832).

SULPHOCYANATES. Synthesis of *Ammonium Sulphocyanate*.—According to Berthelot (*Jahresb. f. Chem.* 1868, 160), carbon sulphide is not acted upon by gaseous ammonia at ordinary temperatures, even after several hours' contact. Heys van Zouteveen, on the other hand (*Archives Néerlandaises*, v. 240), finds that when dry ammonia gas is passed into carbon sulphide, a brick-red precipitate is formed, the aqueous solution of which, when evaporated over a Bunsen flame to half its bulk, becomes decolorised, gives off vapours of carbon sulphide and ammonium sulphide, and deposits a small quantity of sulphur, leaving a solution of ammonium sulphocyanate, as shown by its reaction with ferric salts.

The first stage of the reaction appears to be:

analogous to—

(1st *Suppl.* 408), the ammonium sulphocarbamate thus formed being subsequently decomposed by the action of heat on its aqueous solution, as shown by the equation:

The process may also be supposed to take place as follows: first—

and then, on boiling the mixture:

Mercurio Sulphocyanate.—The following double salts of this compound have been prepared and analysed by Th. Nordström (*Deut. Chem. Ges. Ber.* iv. 989).

Potassium Isosulphocyanate, $\text{N} \left\{ \begin{smallmatrix} \text{CS} \\ \text{K} \end{smallmatrix} \right.$.—This salt is obtained by the action of alcoholic potash on persulphocyanic acid, as a yellow granular mass, which may be decolorised by boiling with very strong alcohol, and freed from adhering water by exposure over oil of vitriol. It dissolves easily in water, is nearly insoluble in strong alcohol, but soluble in very weak spirit. By leaving the aqueous solution for some time in a vacuum over sulphuric acid, it is obtained in crystals having the composition $2\text{KNCS} + \text{H}^{\text{o}}\text{O}$. The following reactions distinguish the isosulphocyanate from the ordinary sulphocyanate:

	Sulphocyanate	Isosulphocyanate
Silver nitrate .	White precipitate, soluble in ammonia .	Light yellow precipitate, scarcely soluble in ammonia
Basic acetate of lead	White voluminous precipitate . . .	Yellow precipitate
Copper sulphate	Black pulverulent precipitate . . .	Greenish-yellow precipitate
Cobalt sulphate .	Rose-red coloration . . .	Brownish-green precipitate
Nickel sulphate .	Greenish coloration . . .	Roddish precipitate
Cadmium sulphate	White precipitate
Zinc chloride .	No reaction . . .	Deep yellow, voluminous precipitate
Mercuric chloride	White voluminous precipitate
Mercurous nitrate .	Grey precipitate . . .	Black precipitate

Ferric chloride gives, with neutral solutions of the isosulphocyanate, a brown coloration, which disappears on adding excess of the iron solution; a yellow pulverulent body separates from the liquid on standing.

Potassium isosulphocyanate may be partially converted into sulphocyanate by repeated evaporation of its aqueous or weak alcoholic solution on the water-bath, and completely by fusion.

A smell, similar to that of mustard-oil, is observed on leaving ethyl iodide in contact with isosulphocyanate of potassium or silver (*Fleischer, Deut. Chem. Ges. Ber.* iv. 190).

Sulphocyanic Ethers. *Allyl Isosulphocyanate* or *Sulphocarbimide*.

Volatile Oil of Mustard. $\text{N} \left\{ \begin{smallmatrix} (\text{CS})^{\text{v}} \\ \text{C}^{\text{H}}\text{H} \end{smallmatrix} \right.$. According to Vollrath (*Arch. Pharm.* [2], cxlviii. 156), this oil forms an essential constituent of the root of mignonette. It mixes with strong sulphuric acid without coloration. On adding 3 pts. of strong sulphuric acid drop by drop to 1 pt. of mustard oil, both being cooled by ice, decomposition sets in, attended with evolution of sulphurous acid and carbon oxy-sulphide (*Flückiger, Arch. Pharm.* [2], cxlv. 214; *Chem. Soc. J.* [2], ix. 835).

Mustard-oil unites directly with *acid potassium sulphite*, when boiled with it in concentrated solution, forming the compound $\text{C}^{\text{H}}\text{H}^{\text{a}}\text{NS}.\text{SO}^{\text{a}}\text{KII}$, which separates on evaporation in yellowish crystals, and may be obtained by recrystallisation in colourless nacreous laminae, decomposing at 90° – 100° . The *silver* and *lead* compounds formed from it by double decomposition likewise decompose very quickly. The potassium salt distilled with strong potash-solution yields ammonia, sulphide and thiosulphate of potassium, and allylamine. With strong sulphuric acid it gives off sulphurous oxide, and an oil boiling at 140° , and probably consisting for the most part of allyl sulphide (*Böhler, Ann. Ch. Pharm.* cliv. 59).

On the use of mustard-oil for preserving milk, see p. 811.

Phenyl Isosulphocyanate, $\text{N}(\text{CS})^{\text{v}}(\text{C}^{\text{H}})^{\text{a}}$. (*Losanitsch, Deut. Chem. Ges. Ber.* iv. 156). An alcoholic solution of *chloraniline*, treated with carbon bisulphide gives

1118 SULPHOCYMENIC—SULPHOFUMARIC ACID.

Chlorophenyl sulphocarbamide, $\text{CS} \begin{Bmatrix} \text{NH}(\text{C}^6\text{H}^4\text{Cl}) \\ \text{NH}(\text{C}^6\text{H}^4\text{Cl}) \end{Bmatrix}$, and the alcoholic solution of this substance, treated with alcoholic iodine solution, yields chlorophenyl isosulphocyanate or sulphocarbimide, $\text{N} \begin{Bmatrix} \text{CS} \\ \text{C}^6\text{H}^4\text{Cl} \end{Bmatrix}$, in colourless needles melting at 40° . This compound reacts with ammonia in the same manner as the other isosulphocyanic ethers, yielding a chlorinated phenyl-carbamide having the composition $\text{CS} \begin{Bmatrix} \text{NH}(\text{C}^6\text{H}^4\text{Cl}) \\ \text{NH} \end{Bmatrix}$. Heated with water in sealed tubes to 130° , the chlorophenyl isosulphocyanate is resolved into carbon dioxide, hydrogen sulphide, and chloraniline. With absolute alcohol, on the other hand, it yields a semi-sulphuretted chlorophenylurethane, $\text{CS}(\text{C}^6\text{H}^4\text{Cl})\text{HN} \begin{Bmatrix} \text{C}^6\text{H}_5 \\ \text{O} \end{Bmatrix}$.

Iodaniline behaves with carbon bisulphide similarly to chloraniline. In the formation of the corresponding iodated phenyl isosulphocyanate, a residuo is obtained, which, by treatment with alkali and precipitation by acid, gives iodated triphenyl-

A corresponding compound appears also to be formed in the preparation of the chlorophenyl isosulphocyanate.

Propyl Sulphocyanate, $\text{S} \begin{Bmatrix} \text{CN} \\ \text{C}^3\text{H}_7 \end{Bmatrix}$, formed by treating an alcoholic solution of propyl bromide with potassium sulphocyanate, is a fetid oil boiling at 163° (Carl Schmitt, *Zeitschr. f. Chem.* [2], vi. 576).

SULPHOCYMENIC ACID. Syn. with CYMENK-SULPHONIC ACID (p. 420).

SULPHODIALURIC ACID. See SULPHOSKUDO-URIC ACID (p. 1125.)

SULPHODIBROMOBENZENE and SULPHODIBROMONITROBENZENE. Syn. with DIBROMOBENZENESULPHONIC and DIBROMONITROBENZENESULPHONIC ACIDS (pp. 153, 154).

SULPHOFORM, $\text{C}^2\text{H}^2\text{S}^2$, appears to be produced by heating sulphur with iodoform in sealed tubes to a temperature not exceeding the melting point of sulphur. On mixing an alcoholic solution of potassium sulphide with chloroform, reaction takes place with explosive violence, and a compound of sulphoform with potassium sulphide is produced, which crystallises from alcohol in long prisms (Pfankuch, *J. pr. Chem.* [2] iv. 38; vi. 97).

SULPHOFUMARIC ACID, $\text{C}^4\text{H}^4\text{SO}^2 = \text{C}^4\text{H}^4\text{SO}^2\text{H}(\text{CO}^2\text{H})^2$, (Credner, *Zeitschr. f. Chem.* [2], vi. 77). This acid is produced by boiling fumaric acid for a considerable time with a solution of acid potassium sulphite and potassium carbonate. On precipitating the resulting solution with lead acetate, and decomposing the precipitate with hydrogen sulphide, a solution is formed containing an acid potassium salt; to prepare the free acid, this solution must be neutralised with ammonia, and again precipitated with lead acetate.

Sulphofumaric acid forms a syrupy, strongly acid liquid, which, when left for some time over sulphuric acid, deposits indistinct crystals deliquescent immediately on exposure to the air. It is tribasic, and forms basic and acid salts. The *potassium salt*, $\text{C}^4\text{H}^4\text{K}^3\text{SO}^2 + \text{H}^2\text{O}$, forms nodular groups of efflorescent crystals. The above-mentioned acid potassium salt likewise forms nodules having the composition $(\text{C}^4\text{H}^4\text{K}^3\text{SO}^2) \cdot \text{C}^4\text{H}^4\text{SO}^2 + 1\frac{1}{2}\text{H}^2\text{O}$; when heated on platinum foil, it swells up like mercuric sulphocyanate. The *acid ammonium salt*, $\text{C}^4\text{H}^4(\text{NH}^4)^3\text{SO}^2$, prepared by saturating 1 pt. of the acid with ammonia, and adding 2 pts. of acid, forms crystals. The *silver salt*, $\text{C}^4\text{H}^4\text{Ag}^3\text{SO}^2$, obtained by precipitating the neutral potassium salt with silver nitrate, is white, crystalline, and moderately soluble in water. The *barium salt*, $(\text{C}^4\text{H}^4\text{SO}^2)^2\text{Ba}^2$, is obtained by precipitation. The *calcium salt*, $(\text{C}^4\text{H}^4\text{SO}^2)^2\text{Ca}^2 + 6\text{H}^2\text{O}$, forms colourless efflorescent laminae. The *neutral lead salt*, $(\text{C}^4\text{H}^4\text{SO}^2)^2\text{Pb}^2 + 4\text{H}^2\text{O}$, formed by precipitating the acid potassium salt with lead acetate, is soluble in water, free acid, and solution of lead acetate. A basic insoluble lead salt, $(\text{C}^4\text{H}^4\text{SO}^2)^2\text{Pb}^2 \cdot 2\text{PbO}$, is obtained by precipitating a solution of the acid potassium salt neutralised with ammonia. The *copper salt* is uncrystallisable.

Sulphofumaric acid heated with strong potash-ley is resolved into sulphurous and fumaric acids. With zinc and hydrochloric acid it gives off hydrogen sulphide. On treating it with hydrochloric acid alone, sulphurous acid is evolved and fumaric acid reproduced.

SULPHOGALLOLIC—SULPHOPHENYLPROPIONIC ACID. 1119

SULPHOGALLOLIC ACID, $C^6H^4SO^4 = C^6H^3\{(OH)^1\}_{SO^2OH^1}$ (Schiff, *Deut. Chem. Ges. Ber.* v. 642). An acid produced by treating recrystallised pyrogallol with pure disulphuric acid (obtained by adding 1 mol. SO^2 to 1 mol. SO^2H^2). A mixture of 25 grams of pyrogallol and 10 a.c. of the acid mixture became hot and solidified in two minutes, and after ten minutes' further warming, the pyrogallol was completely converted into a slightly coloured sulphogallolic acid. This acid is much more soluble than gallic acid, and deliquesces on exposure to the air. Its *potassium salt*, $C^6H^3(OH)^1SO^2K + 2H^2O$, crystallises in large rhombic octohedrons. The *silver salt*, $C^6H^3(OAg)^1SO^2Ag$, forms crystalline grains.

Sulphogallolic acid when heated, loses water, and is converted into sulphotannic acid, $C^{12}H^8S^2O^{11} = 2C^6H^4SO^4 - H^2O$ (p. 1125).

SULPHOMALEIC ACID, $C^4H^2SO^2 = C^4H^2(SO^2H)(CO^2H)^2$ (Strecker & Messel, *Zeitschr. f. Chem.* [2], vi. 459). This acid, isomeric with sulphofumaric and sulphosuccinic acid (v. 527), is obtained in indistinct crystals by decomposing its silver salt with hydrogen sulphide. When fused with potash, it yields nothing but fumaric acid. The *neutral potassium salt* has the composition $C^4H^2K^2SO^2 + H^2O$ (the sulphosuccinate crystallises with $3H^2O$). Its solution gives with lead acetate a heavy white precipitate, which, when decomposed by hydrogen sulphide, yields an *acid potassium salt*, $C^4H^2KSO^2$, crystallising from alcohol in small transparent crystals, and precipitated by alcohol from its aqueous solution as a pasty mass, which hardens in the air, and swells up when heated like mercuric sulphocyanate. The solution of this salt, mixed with lead acetate, gives a bulky precipitate of the salt, $(C^4H^2SO^2)^2Pb^2$, which becomes crystalline on standing. The *potassium salt* obtained directly in the preparation of the acid by boiling maleic acid with neutral potassium sulphite has the composition $C^4H^2K^2SO^2$. The *barium salt*, $(C^4H^2SO^2)^2Ba^2$, is slightly soluble in cold, more freely in hot water. A calcium salt with probably 1 at. Ca is obtained by boiling the acid with calcium carbonate; the neutral salt by neutralisation with milk of lime. The *silver salt*, $C^4H^2Ag^2SO^2$, prepared from the potassium salt above mentioned by the action of ammonia, forms a heavy precipitate, slightly soluble in cold, more soluble in hot water.

SULPHOMESITYLENIC ACID. Syn. with MESITYLENE-SULPHONIC ACID (p. 788).

SULPHONAPHTHALIC ACID. Syn. with NAPHTHALENE-SULPHONIC ACID (p. 835).

SULPHONAPHTHOIC ACID. See NAPHTHOIC ACID (p. 838).

SULPHOPALLADATES. See PALLADIUM (p. 889).

SULPHOPARA-OXYBENZOIC ACID (R. Koelle, *Ann. Ch. Pharm.* clxiv. 150-164). This acid is produced by acting with the vapour of sulphuric anhydride on dry para-oxybenzoic acid; a syrupy brown mass is thereby formed, which is to be diluted with water and neutralised with quicklime. The solution of the calcium salt is precipitated with potassium carbonate, and lead acetate is added to the filtrate. The bulky precipitate, which is insoluble in water, is decomposed by hydrogen sulphide, and the solution of the free acid is evaporated on a water-bath. The crude acid thus obtained is purified by dissolving it in absolute alcohol, evaporating the solution, and recrystallising the residue from water. The acid is very soluble in water and alcohol, crystallises in deliquescent, white, silky needles, and gives a blood-red colour with ferric chloride.

On evaporating a solution of the potassium salt, quadratic plates, having the composition $C^6H^4K^2SO^4 + 2H^2O$, crystallise out, and from the mother-liquor the salt, $C^6H^4K^2SO^4 + H^2O$, is obtained in needles. Both salts contain the same acid, as the latter salt, by addition of caustic potash, may be converted into the quadratic salt, and as both, when fused with caustic potash, yield protocatechuic acid.

The *neutral barium salt*, $2C^6H^4BaSO^4 + 7H^2O$, crystallises from water in small plates, and a *basic salt*, $(C^6H^4SO^4)Ba$, is obtained as an amorphous powder by adding barium chloride to a solution of the basic potassium salt. The *silver salt*, $C^6H^4Ag^2SO^4$, separates from a hot aqueous solution in crystalline flakes. The *copper salt*, $C^6H^4CuSO^4$, remains, on evaporating its solution, as a dark-green amorphous powder; the *cadmium salt*, $C^6H^4CdSO^4 + 3H^2O$, forms microscopic crystals, and is readily soluble in water.

SULPHOPHENOLIC ACIDS. Syn. with PHENOLSULPHONIC ACIDS (p. 917).

SULPHOPHENYLPROPIONIC ACID, or **PHENYLSULPHOPROPIONIC ACID**, $C^9H^7SO^3 = C^9H^6\{(OH)^1\}_{CO^2H^1}$ is formed as an acid potassium salt by the action of neutral potassium sulphite on cinnamic acid:
 $C^9H^7O^2 + SO^2HK = C^9H^7SO^3K$

The two bodies unite directly when boiled together for twelve hours in aqueous solution (1 pt. potassium sulphite to 10 water). The *acid potassium salt* crystallises in stellate groups of hard needles, soluble in 25.9 pts. of water at 15°, more easily in hot water, sparingly in alcohol. It crystallises without alteration from boiling dilute hydrochloric or sulphuric acid, melts and decomposes when heated. The *neutral potassium salt*, $C^2H^3SO^3K^2$ (dried at 120°), crystallises from water in colourless transparent crystals, from alcohol in nodules; it contains water of crystallisation and effloresces in contact with the air. By boiling the acid salt with zinc or zinc oxide, a *zincopotassic salt*, $(C^2H^3SO^3)^2ZnK^2$, is produced. The *silver salt* is a white crystalline precipitate. The *lead salt*, obtained by boiling the acid potassium salt with lead hydrate, is a viscid mass while hot, but becomes brittle on cooling.

Phenylsulphopropionic acid, obtained by decomposing the lead salt with hydrogen sulphide, forms colourless easily soluble crystals. It is not altered by boiling with strong hydrochloric or dilute sulphuric acid, but is carbonised by strong sulphuric acid. Strong nitric acid converts it into a nitro-acid. Potassium chromate and sulphuric acid act upon it only in concentrated solution. Strong potash-ley converts it into cinnamic acid (C. Valet, *Ann. Ch. Pharm.* cliv. 62).

SULPHOPHOSPHORIC ETHERS. These compounds are phosphoric ethers in which the oxygen is more or less replaced by sulphur. A few of them were obtained by Carius in 1859, by the action of phosphorus pentasulphide on alcohol (iv. 592). More recently (*Ann. Ch. Pharm.* cxix. 289) Carius has obtained nearly the entire series of the ethylsulphophosphoric ethers, and has shown that, both in mode of formation and in chemical reactions, these sulphur-compounds are exactly analogous to the corresponding oxygen-compounds, and that the sulpho-alcohols yield ethers in the same manner as the oxygen-alcohols. Some of the corresponding methyl- and amyl-compounds have been prepared by Kovalevsky (*ibid.* cxix. 303).

The sulphophosphoric ethers exhibit isomerism of such a kind that one of the two bodies has the sulphur, the other the oxygen, outside the radicle; but this difference of structure is not accompanied by any difference of properties; e.g. $(C^2H^3)^2 \overset{PS}{O}$ is identical in properties with $(C^2H^3)^2 \overset{PO}{S}$.

The diethylic and triethylic orthosulphophosphoric ethers are formed: (1), by the action of the hydrates or sulphhydrates; (2), by that of the oxides or sulphides of alcohol-radicles, on the pentoxide or pentasulphide of phosphorus; or (3) by the action of the oxychloride or sulphochloride of phosphorus on alcohol or mercaptan respectively:

1. **NEUTRAL OR TRIETHYLIC ORTHOSULPHOPHOSPHORIC ETHERS.** These ethers are liquids which do not solidify at -18° , and have an aromatic odour inclining more and more to alliaceous in proportion to the quantity of sulphur which they contain. Those which contain only oxygen or only sulphur, $PO(OC^2H^3)^3$, and $PS(SC^2H^3)^3$, volatilise without decomposition, the former at about 200° , as colourless liquids which soon turn red. The three intermediate oxysulpho-ethers, $PS(OC^2H^3)^2(SC^2H^3)$, $PO(SC^2H^3)^2(OC^2H^3)$, and $PS(OC^2H^3)(SC^2H^3)^2$, are decomposed by heat, giving off ethyl sulphide, with violent ebullition, towards 160° ; the monosulphuretted ether at the same time gives off ethyl oxide and partly distills undecomposed. The mono- and di-sulphuretted ethers distil undecomposed with vapour of water; the tri- and tetra-sulphuretted ethers are decomposed thereby, with evolution of mercaptan and sulphuretted hydrogen. *Alkalies and alkaline sulphides*, especially in alcoholic solution, convert these neutral

ethers into diethylic acids of the same degree of sulphuration; ethyl tetrasulphophosphate yields at the same time diethylic acids of lower boiling point. The neutral ethers, heated with *alcohol* in sealed tubes, yield the diethylic acid containing 1 at. sulphur less, together with the mono- or di-sulphide of the alcohol-radicle. With strong *sulphuric acid*, the neutral ethers decompose in the following manner, yielding a sulphuretted pyrophosphoric ether, together with ethylsulphuric acid:

A similar action is exerted by very concentrated solutions of *phosphoric acid* and *calcium chloride*. By the further action of sulphuric acid, sulphur dioxide is evolved and neutral ethers of the metaphosphoric series are produced. Ethylic tetrasulphophosphate, however, does not exhibit the reactions just mentioned.

Phosphorus pentachloride forms, with the triethylic orthosulphophosphates, ethyl chloride, phosphoryl chloride—or, in the case of the tetrasulphophosphate, sulphophosphoryl chloride—and a diethylic chloride:

If the pentachloride is in excess, the action goes further, producing a monethylic dichloride, or finally sulphophosphoryl chloride:

A similar action takes place with phosphorus iodide, or with iodine and phosphorus. The triethylic ethers form well-crystallised compounds with the chlorides and iodides of lead, silver, and especially mercury.

2. **DIETHYLIC ORTHOSULPHOPHOSPHORIC ACIDS.**—*Diethyltetrasulphophosphoric acid*, $\text{PS}(\text{SC}^2\text{H}^5)^2\text{SH}$, the end-product of the series, is the only one of these acid ethers which is obtained directly in the pure state; it crystallises in beautiful sulphur-yellow, transparent prisms from its solution in triethylic tetrasulphophosphate, which is the final product of the action of phosphorus pentasulphide on mercaptan. The others have to be separated by hydrogen sulphide from the pure alcoholic solutions of their lead, mercury, or silver salts.

Diethylmono- and *Diethyldi-sulphophosphoric acids* are colourless, viscid, very acid liquids, which, when left to evaporate in a vacuum, slowly yield needle-shaped crystals; they smell like butyric acid and deliquesce in contact with the air.

The three acids just described, as well as *diethyltrisulphophosphoric acid*, are decomposed when heated to 100° , with formation of mercaptan. On boiling the aqueous solution of diethyldisulphophosphoric acid, hydrogen sulphide is abundantly evolved, and diethylmonosulphophosphoric acid is formed:

By prolonged boiling the monosulphuretted acid is decomposed in a similar manner.

Diethyltrisulphophosphoric acid is decomposed by water in like manner, even at ordinary temperatures, and cannot be separated unchanged by evaporation from its alcoholic solution. *Diethyltetrasulphophosphoric acid* decomposes in a similar manner, at the same time that it deliquesces in the air; when it is directly dissolved in water, the recently prepared solution contains small quantities of tetrasulphophosphoric acid.

The four compounds above described belong to the strongest acids. Their salts may be obtained by direct neutralisation of the acid with metallic oxides or carbonates; those which are insoluble, also by precipitation; the diethyltetrasulphophosphates, however, are obtained only by precipitating the ethereal solution of the acid with the ethereal solutions of metallic salts. In the dry state these salts—excepting those of the alkalis and alkaline earths, which are deliquescent—resist perfectly the action of light and air; only the silver and mercury salts of diethyltri- and diethyltetra-sulphophosphoric acid blacken slightly at ordinary temperatures. When heated they decompose with greater facility in proportion as they contain more sulphur; at a red-heat the diethylmonosulphates alone leave the whole of their phosphorus in the form of metaphosphate.

The ammonium, potassium, barium salts, &c., of the four acids are easily soluble.

in water; those of diethylmonosulphophosphoric acid with the metals of the magnesium-group, are slightly soluble; all the rest are insoluble and form heavy, curdy precipitates. The last-mentioned salts melt for the most part, without decomposition, and dissolve easily in hot alcohol, ether, or benzene, from which solutions they crystallise very beautifully on cooling. Diethylmonosulphophosphoric acid and its salts in aqueous or alcoholic solution form with ferric salts a brown flocculent precipitate slightly soluble in absolute alcohol; the more highly sulphuretted acids, on the contrary, form deep black crystalline precipitates soluble with ruby-red colour in alcohol.

All the salts above described are decomposed by ordinary acids in the cold with great difficulty or not at all; but by strong sulphuric acid, at a gentle heat, they are converted into neutral ethers of the tetrabasic or pyrophosphoric series; thus (R denoting a monatomic metal):

With phosphorus pentachloride they behave like the neutral ethers:

Ethylsulphophosphoric chlorides.—The mode of formation of these compounds has been already explained (p. 1121). Only two have actually been obtained, viz.: $\text{PS}(\text{OC}^2\text{H}^3)^2\text{Cl}$ and $\text{PS}(\text{OC}^2\text{H}^3)(\text{SC}^2\text{H}^3)\text{Cl}$. They are heavy, pungent liquids undistillable or not completely distillable without decomposition. They decompose slowly with water, more quickly with alcoholic solutions of the alkalis, forming diethyl chlorides of the diethylated acids; and the bodies of these two classes act on one another in such a manner as to form neutral pyrosulphophosphoric ethers:

3. METHYLIC and AMYLIC ORTHOSULPHOPHOSPHORIC ETHERS (Kovalevsky, *Ann. Ch. Pharm.* cxix. 303).—Methyl alcohol is strongly attacked by phosphorus pentasulphide, and converted, with copious evolution of hydrogen sulphide, into a viscid liquid, which is a solution of *dimethyl-disulphophosphoric acid*, $\text{PS}(\text{OCH}^3)^2(\text{SH})$, in *trimethyl disulphophosphate*, $\text{PS}(\text{OCH}^3)^2(\text{SCH}^3)$:

The reaction must at first be moderated by cooling, afterwards promoted by heat, till all the phosphorus sulphide is dissolved. *Trimethyl disulphophosphate*, separated from the product by water, and dried under the air-pump or in a current of air at 40° , is a colourless, oily, fetid liquid, not solidifying at -12° , slightly heavier than water. It decomposes at 150° , evolving fetid products, but distils almost undecomposed with aqueous vapour; it dissolves easily in dilute alcohol, and in this solution is gradually converted into dimethylphosphoric acid. When heated with alcohol it is resolved into dimethyl-monosulphophosphoric acid and methyl-ethyl sulphide, probably thus:

With *strong sulphuric acid* it forms methylsulphuric acid and an oil separable by water, regarded by Kovalevsky as a mixture of methyl tetrasulphophosphorylphosphate, with an ether of the meta-series. With *phosphorus pentachloride* it yields, together with ethyl chloride and phosphorus oxychloride, a liquid compound—probably dimethyl oxydisulphochloride, $\text{PS}(\text{OCH}^3)(\text{SCH}^3)\text{Cl}$ —resolved by alkalis into metallic chloride and dimethyl disulphophosphate. With *mercuric iodide* the trimethyl ether forms a compound which crystallises in needles and reacts like the corresponding ethyl-compound.

Dimethyl-disulphophosphoric acid, $\text{PS}(\text{OCH}^3)^2(\text{SH})$, is obtained by digesting the watery liquid separated from the trimethyl ether just described with lead carbonate at 30° – 40° , precipitating the filtrate with lead acetate, crystallising the washed precipitate from absolute alcohol, and decomposing the lead salt in alcoholic solution with hydrogen sulphide. On evaporating finally under the air-pump, the dimethylated acid remains as an acid, viscid liquid which decomposes below 100° . The salts which it forms with the alkalis and alkaline earths dissolve easily in water, and are best prepared by treating the lead salt with alkaline sulphides. The dimethyl-disulphophosphates of the heavy metals are curdy precipitates which crystallise from hot ether, alcohol, or benzene. The *lead salt*, $\text{PS}(\text{OCH}^3)^2\text{SPb}$, crystallises in shining prisms often an inch long, permanent in the air and melting below 100° . The *mercuric salt*, $\text{PS}(\text{OCH}^3)^2\text{SHg}$, is more decomposable and less soluble in alcohol.

Amyl alcohol digested at a gentle heat with phosphorus pentasulphide forms *triethyl tetrasulphophosphate* and *diethyl-disulphophosphoric acid*, probably thus:

On treating the viscid product with cold water, the acid ether passes into solution, while the triamyl ether separates as a viscid yellow body. The latter is insoluble in water, mixes with absolute alcohol, and decomposes at 100° or when boiled with water. *Diethyl-disulphophosphoric acid*, separated from the aqueous solution in the same manner as the corresponding methyl-compound, is an acid, colourless syrup, already mixed with products of decomposition. Its salts react like those of the dimethyl acid. The lead salt, $\text{PS}(\text{OC}^2\text{H}^5)^2\text{SPb}$, melts below 70° , dissolves easily in absolute alcohol, and crystallises in small, four-sided rhombic plates, or in monoclinic prisms.

4. PYROSULPHOPHOSPHORIC ETHERS (Carins, *Ann. Ch. Pharm.* cxix. 298). These ethers are formed: 1. By abstraction of $(\text{OC}^2\text{H}^5)^2$ from 2 mols. of a neutral ortho-sulphophosphoric ether, by the action of strong sulphuric acid, &c. (p. 1025). 2. By abstraction of the elements of a metallic oxide, R^2O or $\text{R}'^2\text{O}$, from 2 mols. of a salt of a diethyl acid of the ortho-series, by the action of hydrogen sulphate on phosphorus oxychloride (a very large excess of salt being used in the latter case):

3. By the action of the diethyl-chlorides of the ortho-series on the diethyl acids of the same series, or on their salts, or neutral ethers, e.g.:

Tetreehtic Disulphopyrophosphate, $(\text{PS})^2(\text{OC}^2\text{H}^5)^4\text{O}$, is a colourless, nearly scentless oil, moderately soluble in water without decomposition; it begins to boil, with simultaneous decomposition, somewhat below 160° . On distilling it with vapour of water, the greater part passes over undecomposed, while the remainder takes up the elements of water, and is converted into *diethyl-orthosulphophosphoric acid*. Treated with a quantity of alcoholic potash not sufficient to decompose it completely, it is converted into *potassium triethyl-disulphopyrophosphate*, from which the free acid cannot be separated without alteration, since at the moment of separation it takes up the elements of water.

Trisulphopyrophosphoric Bromotriethylin, $\text{P}^2\text{S}^4(\text{OC}^2\text{H}^5)^4\text{Br} = \text{C}^2\text{H}^5\text{O} \begin{matrix} \diagup \\ \text{PS} \end{matrix} \text{S} \begin{matrix} \diagdown \\ \text{PS} \end{matrix} \begin{matrix} \diagup \\ \text{OC}^2\text{H}^5 \\ \text{Br} \end{matrix}$. — This compound is formed when pyrophosphoric sulphobromide (p. 063) is slowly poured into alcohol distilled from sodium. The resulting liquid when poured into water yields a yellow oil consisting of the two ethers, $\text{P}^2\text{S}^4(\text{OC}^2\text{H}^5)^4\text{Br}^2$ and $\text{P}^2\text{S}^4(\text{OC}^2\text{H}^5)^4\text{Br}$. But on redissolving it in alcohol, leaving the solution to stand for some time, and again pouring it into water, only the triethylated body is obtained, the substitution of ethoxyl for bromine taking place with difficulty in presence of much hydrogen bromide.

The bromotriethylin is a yellow, transparent liquid having an ethereal odour, recalling however that of the sulphobromide. Its specific gravity is 1.3567 at 19° . It cannot be distilled without decomposition, and it fumes slightly in the air after exposure to it for some time. It is slowly decomposed by water and aqueous alkalis, with separation of sulphur. Alcoholic solutions decompose it more quickly, producing mercaptan-like bodies, phosphoric acid, and bromide of the metal (Michaelis, *Ann. Ch. Pharm.* clxiv. 9).

Tetreehtic Trisulphopyrophosphate, $\text{PS}^3(\text{OC}^2\text{H}^5)^6 = \text{C}^2\text{H}^5\text{O} \begin{matrix} \diagup \\ \text{PS} \end{matrix} \text{S} \begin{matrix} \diagdown \\ \text{PS} \end{matrix} \begin{matrix} \diagup \\ \text{OC}^2\text{H}^5 \\ \text{OC}^2\text{H}^5 \end{matrix}$, is formed by the further action of alcohol on the triethylated bromide just described. The latter is dissolved in three times its volume of alcohol, and the solution, after being left for some hours, at 40° , and then cooled, is precipitated by water. It is a yellow, faintly aromatic liquid, smelling somewhat like turpentine. Sp. gr. 1.1892 at 170° . It can be distilled with steam with only partial decomposition. Heated to 60° with alcoholic ammonia in a sealed tube, it is decomposed, yielding a white amorphous substance, which is probably the amide, $\text{PS}^3(\text{NH}^2)^3$ (Michaelis).

Ethylic Tetrasulphopyrophosphate has not yet been obtained pure; it appears to be a solid, easily fusible body (Carius).

Tetreethyl Pentasulphopyrophosphate, $P^2S_5(OC^2H^5)^4(SC^2H^5)^2$, is formed by the action of strong sulphuric acid on triethylic disulphorthophosphate (p. 1120) (Carius). It is also deposited during the drying of the trisulphopyrophosphoric ether just described, in small white crystals, and may be separated from the liquid by filtration through asbestos. It is obtained in much larger quantity by treating trisulphopyrophosphoric sulphobromide at 40° , with aqueous instead of absolute alcohol, and most abundantly of all by the action of alcohol on the impure metaphosphoric sulphobromide obtained in the preparation of the pyrobromide (p. 963). In this case there appears to be no action at first, but after some time the mixture becomes hot, the greater part of the metabromide disappears, and as the liquid cools, the tetreethylic pentasulphopyrophosphate separates out in large crystals (Michaelis). It melts at 71.2° , and is especially distinguished by the facility with which it may be converted into a salt of diethylsulphophosphoric acid (Carius):

Theoretically, it should be susceptible of two isomeric modifications, viz.:

5. **ETHYLIC MONOSULPHOMETAPHOSPHATE**, $PS \left\{ \begin{array}{l} OC^2H^5 \\ O \end{array} \right.$, is formed by the prolonged action of hydrogen sulphate on tetreethylic monosulphophosphate:

SULPHOPYROTARTARIC ACID, $C^2H^4SO^4$ (T. Wieland, *Ann. Ch. Pharm.* clvii. 34). This acid is formed by direct combination of the three isomeric pyrocitric acids, $C^2H^4O^4$, with alkaline sulphites. When neutral potassium sulphite is boiled for several hours in moderately concentrated solution with itaconic acid, potassium sulphopyrotartrate is formed, and may be obtained in the form of a syrup by evaporation, or as a gummy mass by precipitation with alcohol. Its solution gives pasty precipitates with barium or lead acetate, but is not precipitated by iron, copper, mercury, or zinc salts. With calcium chloride it gives a crystalline calcium salt, $(C^2H^4SO^4)^2Ca^2 + 7H^2O$, which gives off 5 mols. water at 110° , another at 160° , becomes anhydrous at 180° , and decomposes between 190° and 200° . It dissolves easily in hot, sparingly in cold water. By treating it with sulphuric acid and dilute alcohol, and evaporating the filtrate, sulphopyrotartaric acid is obtained in indistinct crystals. By partially neutralising the acid with carbonate of potassium or ammonium, acid salts are obtained in nodular groups of crystals, easily soluble in water, less soluble in dilute alcohol, quite insoluble in strong alcohol.

Citraconic and mesaconic acids treated with potassium sulphite yield sulpho-acids, which appear to be identical with that obtained from itaconic acid.

SULPHOPSEUDO-URIC ACID, $C^2H^4N^4SO^4$ (Nencki, *Deut. Chem. Ges. Ber.* iv. 722; v. 451). This acid is obtained by heating a mixture of 2-3 grms. sulphocarbamide and the equivalent quantity of alloxan, with concentrated alcoholic solution of sulphurous anhydride in sealed tubes to 100° for about five hours. The product is purified by repeated treatment with concentrated ammonia to remove uramil; dissolution in caustic soda, rise of temperature being carefully avoided; filtration; precipitation with solution of ammonium chloride, to remove sulphur; and recrystallisation from very concentrated hydrochloric, or better hydrobromic acid, from which it separates on cooling in concentric groups of slender needles. It is probably formed according to the equation:

Sulphopseudo-uric acid is insoluble in water and ammonia, difficultly soluble in hydrochloric, but more readily in hydrobromic and sulphuric acids, being reprecipitated on the addition of water. All attempts to remove the sulphur from it have been unsuccessful. It is readily soluble in the fixed alkalis, even in the cold; on warming, the solution becomes yellow, and then contains the alkaline salt of a compound, precipitable from the very dilute solution by hydrochloric acid in the form of silky, glistening, microscopic plates, which on analysis gave numbers agreeing both with the formula of hydrated sulphoalloxantin, $C^2N^2SO^2H^2 + 2nq$, and of sulphodialuric

acid, $C^6H^4SO^2H^1 + 1\frac{1}{2} aq$. The instability of this substance renders a determination of the water of crystallisation difficult.

When sulphopseudo-uric acid is heated with twice its weight of strong sulphuric acid to 150° – 160° , a small quantity of sulphurous oxide is evolved, and urosulphinic acid, $C^6H^4N^1SO^2$, is formed—a weak monobasic acid, derived from sulphopseudo-uric acid by abstraction of H^2O , and intermediate in chemical character between uric acid and xanthine. If the heating with sulphuric acid be continued, and the temperature raised to 200° , much sulphurous oxide is evolved, the yield of urosulphuric acid is but small, and the solution when evaporated yields a new compound also containing sulphur.

SULPHOSALICYLIC ACID, $C^7H^5SO^2$. When pure salicylic acid is dissolved in ordinary sulphuric acid at a very little heat, and the product is neutralised with calcium carbonate, filtered from gypsum, precipitated by potassium carbonate, decolorised by animal charcoal, and allowed to crystallise, prismatic crystals are obtained, which have the composition $C^7H^5O^4SK^2 + 2H^2O$, do not give off their water of crystallisation below 190° , and begin to decompose at 200° . The mother-liquors of this salt yield another salt which crystallises in quadrate tables very different from the prisms of the former salt; it is much more soluble, and contains $C^7H^5O^4SK^2 + 1\frac{1}{2}H^2O$, the water of crystallisation being given off at 180° , and decomposition commencing at 190° . Neither salt is altered in character by further recrystallisation. Fused potassium hydrate does not act on these compounds so readily as on compounds which contain fewer substituted groups (Ira Ramsen, *Zeitschr. f. Chem.* vii. 296).

SULPHOSUCCINIC ACID, $C^4H^4SO^2$. According to Messel (*Ann. Ch. Pharm.* clvii. 15), this acid, prepared by Fehling's method (v. 527), is identical with sulphomaleic and sulphofumaric acid (p. 1118). Its neutral potassium salt, $C^4H^3K^1SO^2$, however, crystallises with $3H^2O$, whereas the corresponding salts of the other two acids contain only 1 mol. water. Sulphosuccinic acid is converted by fusion with potash into fumaric acid, and by boiling with potash, in the first instance into malic acid (Strecker & Messel, *Zeitschr. f. Chem.* [2], vi. 671).

SULPHOTANNIC ACID, $C^{12}H^8SO^{11}$, is formed by dehydration of sulphogallollic acid, $C^{12}H^8SO^6$ (p. 1119), and may be obtained by gradually heating the crude product of the action of pyrosulphuric acid on pyrogallol with phosphorous chloride to 100° in a flask with reversed condenser. Hydrochloric acid is then given off, and the liquid, after 3 or 4 hours, solidifies to a violet gelatin, which dries up to white floccs over sulphuric acid. Sulphotannic acid closely resembles tannic acid. By boiling with hydrochloric acid it is converted into sulphogallollic acid. Its acetyl-derivative does not exhibit the reactions of tannic acid (Schiff, *Deut. Chem. Ges. Ber.* v. 861).

SULPHOTEREPHTHALIC ACID, $C^8H^4SO^2 = C^8H^4 \begin{matrix} SO^2H \\ CO^2H \end{matrix}$ is prepared by heating terephthalic acid to 200° for six hours with strong sulphuric acid. The barium salt, obtained by pouring the product into water and neutralising the filtrate with barium carbonate, has the composition, $[C^8H^4(CO^2H)SO^2]^2Ba$. When the potassium salt prepared from it is fused with sodium formate, much sulphurous oxide is given off and terephthalic acid is reproduced (Ascher, *Ann. Ch. Pharm.* clxi. 2).

SULPHOTOLUENE, $C^7H^5SO^2$. Syn. with TOLUENE-SULPHONIC ACID (q. v.)

SULPHOTOLUIDE, $C^6H^4SO^2 = C^6H^4 \begin{matrix} ClH \\ SO^2 \\ CH^3 \end{matrix}$. This compound, which

Deville obtained by the action of fuming sulphuric acid on toluene (*Ann. Ch. Pharm.* xlv. 306), has been further examined by Otto & Gruber (*ibid.* cliv. 193). It crystallises from hot alcohol in small tabular prismatic forms, from benzene in vitreous monoclinic prisms; melts at 155° – 156° ; is insoluble in water, slightly soluble in cold alcohol and ether, more soluble in boiling alcohol, benzene, carbon sulphide, and chloroform. It volatilises in small quantities without decomposition; is converted by heating with strong sulphuric acid into toluene-sulphonic acid; dissolves without decomposition in fuming nitric acid; and when heated with a mixture of sulphuric and nitric acids, yields crystallisable nitro-products. It is not altered by strong alcoholic potash even at 160° . Exposed to the action of chlorine in sunshine it deliquesces to an oily mass, probably containing sulphuryl chloride. With chlorine, in diffused daylight, at its melting point, it forms hydrochloric acid and chlorinated products not yet examined. With phosphorus pentachloride it reacts in a similar manner.

SULPHO-UREAS. See SULPHOCARBAMIDES (p. 1115).

SULPHOVALERALDEHYDE, C^3H^4S . See VALERALDEHYDE.

SULPHOXYANTHRAQUINONIC ACID, $C^{14}H^6(O^2)(OH)(SO^2H)$. See 1st Suppl. p. 84.

SULPHOXYALO-ACIDS. See SULPHAZOTISED ACIDS (p. 1111).

SULPHOXYBENZOIC ACID, $C^7H^5O^2SO^2$. This acid, prepared by the action of sulphuric acid on pure oxybenzoic acid, yields, when fused with potash, protocatechuic acid (p. 431) and an isomeric acid less soluble than protocatechuic acid, and forming large, compact, apparently quadratic crystals containing water of crystallisation which is given off at 140° . The acid melts at 189° and gives no coloured reaction with ferric chloride (Ira Remsen, *Zeitschr. f. Chem.* [2], vii. 294).

SULPHUR. *Occurrence.*—This element has been detected spectroscopically in the sun's atmosphere by C. A. Young (*Sill. Am. J.* [3], iv. 356).

The presence of sulphur in Coal-gas may be exhibited by placing a platinum dish containing water over a Bunsen burner, the part of the surface on which the flame impinges becoming coated with a greasy liquid in which sulphuric acid may be detected (Ulex, *Jahresb. f. Chem.* 1871, 207).

On sulphur in Pig-iron, see IRON (pp. 604, 695).

Extraction.—On the extraction of sulphur from sulphuretted ores by roasting, see Tessié du Mothay (*Dingl. pol. J.* cxci. 221); Hasenclover u. Illebig (*ibid.* 284; *Jahresb. f. Chem.* 1871, 980).

On the recovery of sulphur from Soda-waste, see L. Mond (*Dingl. pol. J.* ccii. 266; *Jahresb.* 1871, 1016); Stahlhelm (*Dingl. pol. J.* cxi. 375; *Jahresb.* 1872, 977).

Physical Properties.—On the Spectrum of Sulphur vapour, see Salet (*Compt. rend.* lxxiii. 559; *Chem. Soc. J.* [2], ix. 1145; x. 382; *Jahresb.* 1871, 165; 1872, 141); Ditto (*Compt. rend.* lxxiii. 622; *Chem. Soc. J.* [2], ix. 1146; *Jahresb.* 1871, 170); Gernez (*Compt. rend.* lxiv. 803; *Chem. Soc. J.* [2], x. 382; *Jahresb.* 1872, 139).

On the Heat evolved in the combination of Sulphur with Oxygen, see HEAT (pp. 608-613), with Hydrogen (p. 615).

On the Specific Heat of Sulphur dissolved in Carbon Bisulphide (p. 601).

Modifications.—The properties of amorphous sulphur (v. 531) have been examined by R. Weber (*Pogg. Ann.* cxli. 432). Sulphur, separated from a solution of 1 pt. sodium thiosulphate in $\frac{1}{2}$ to 3 pts. water at about 10° , by stirring with hydrochloric acid, is, a short time after its preparation, almost entirely liquid. The liquid sulphur separated by pressure from a small solidified portion has the colour and consistence of yolk of egg, a specular surface, and a sp. gr. of 1.920, 1.927, 1.926. It solidifies after 24 hours, or sooner, and with evolution of heat, if heated to 100° . The liquid sulphur dissolves almost entirely in carbon sulphide, but the sulphur left on evaporating the solvent contains a portion which no longer dissolves in the carbon sulphide. Stirring the liquid sulphur during solidification renders it partly insoluble in carbon sulphide, the undissolved portion separating as an oily liquid which soon solidifies to a compact or pulverulent mass, accordingly as it has been left at rest or stirred during solidification. If the sulphur, after being brought into a turpentine-like consistence by stirring, be kneaded between the fingers, it becomes very hot, brittle, and crystalline, and then contains a small proportion insoluble in carbon sulphide. The same change is produced in the soft sulphur by diffusing it in a liquid. The sulphur deposited in thin crusts after separation of the greater part of the oily sulphur from the acid solution of the sodium salt, sometimes contains as much as 36 p.c. of insoluble sulphur. Weber regards these results as unfavourable to the supposition that the insoluble sulphur is an immediate product of decomposition of the thiosulphuric acid. Liquid sulphur, separated in the manner above described, almost always contains a small quantity of hydrogen persulphide, which has some influence on the maintenance of the liquid state, like that exerted, according to Diezenbacher (*Jahresb.* 1862, 58; 1865, 127), by small quantities of iodine, bromine, carbon, organic matters, &c.

Sulphur melted with addition of $\frac{1}{4}$ p.c. sulphur chloride, forms, when poured into water, a soft mass which hardens after a few days like ordinary cooled sulphur, and when heated in a water-bath, first becomes almost completely fluid and then solidifies to a crystalline mass with evolution of heat. In this respect it behaves like ordinary soft sulphur, requiring only a somewhat longer time for the transformation, and remaining longer fluid. When immersed in carbon sulphide it is converted into a doughy, ropy mass which partly dissolves, leaving a residue of the consistence of insoluble liquid sulphur, quickly solidifying and converted into a powder by stirring. Sulphur fused with $\frac{1}{4}$ p.c. sulphur chloride and slowly cooled is solid, crystalline, and

otherwise like that above described. Weber's observations do not confirm the statement that crystalline sulphur becomes amorphous in contact with acids, or the view advanced by Berthelot (v. 530), that the sulphur which forms the 'electro-negative element of a compound separates therefrom in the soluble state, whereas that which forms the electro-positive element separates in the insoluble state. Sulphur separated from potassium polysulphide by very dilute nitric acid was found by Weber to contain 86 p.c. soluble sulphur; that which was separated in like manner from hydrogen sulphide contained 74 p.c. insoluble sulphur.

Conversion of Octohedral into Insoluble Sulphur by the action of Sunlight.—When sunlight concentrated by a lens is passed through a solution of sulphur in carbon sulphide contained in a sealed vessel, there is formed at the point where the rays enter the solution, a yellow spot of insoluble sulphur which quickly increases, and at the same time the intensity of the emergent light continually diminishes. Along the whole path of the rays, and especially at the focus, the solution becomes turbid, in consequence of the separation of extremely fine particles of insoluble sulphur. In the spectrum of the emergent light, all the rays between G and H are wanting, as well as the whole of the ultraviolet rays, whereas the part of the spectrum from A to G remains unaltered. It appears, therefore, that the chemical rays are absorbed and expended in molecular work (Lallemand, *Compt. rend.* lxx. 182).

Blue Sulphur.—It is well known that when sulphur is brought in contact with sulphuric anhydride in a certain proportion (1 : 10) a blue liquid is formed. According to W. Stein (*J. pr. Chem.* [2], vi. 178), the colour is due to the circumstance that the sulphur is diffused through the anhydride in a state of very fine division, and may remain suspended in the liquid for weeks like gold-purple. That finely divided sulphur really has a blue colour may be shown by adding a small quantity of ferric chloride to a recently prepared solution of sulphydric acid, the liquid then appearing blue. It is only in transmitted light that the sulphur exhibits this blue colour, and the same is the case with the blue compound of sulphuric anhydride.

Solubility.—Sulphur (in the form of flowers) does not dissolve in a solution of sodium carbonate (containing 5.6 p.c. Na^2CO^3), at 25° , but after ten hours' digestion at 100° , the liquid contains 0.0676 p.c. sulphur (Pohl, *Dingl. pol. J.* cxvii. 508).

Linseed oil mixed with sulphur dissolves the following quantities:

Temperature	25°	60°	95°	130°	160°
Sulphur p.c. dissolved	0.630	1.853	2.587	4.935	9.120

Reactions. 1. With *Vapour of Water.*—According to J. Myers (*Compt. rend.* lxxiv. 195), the action of steam on sulphur at high temperatures produces, not pentathionic acid, as stated by Mulder (*Jahresb.* 1858, 84), but thiosulphuric acid. When steam is passed over boiling sulphur, a slightly acid distillate is obtained, holding in suspension sulphur, which may be removed by agitation with white lead. The filtered solution is resolved at 30° into sulphuric acid and free sulphur, gives a black precipitate with mercurous nitrate, a precipitate of copper sulphide with cupric sulphate, and decolorises iodine-solutions. As this property is not exhibited by tri-, tetra-, or pentathionic acid, but only by sulphurous and thiosulphuric acids, and since the acid in the distillate is resolved by heat into sulphurous acid and sulphur, its identity with thiosulphuric acid is established. That this acid can exist in very dilute aqueous solution is shown by the experiments of H. Rose and Flückiger (v. 629). The reaction between sulphur and water-vapour takes place according to the equation:

Myers also finds that gases, dried by the ordinary means (calcium chloride, strong sulphuric acid, phosphoric anhydride), when passed over boiling sulphur, always give rise to the formation of hydrogen sulphide, and must therefore still contain moisture. He thence infers that the synthesis of hydrogen sulphide from hydrogen and sulphur, observed by many chemists, is really due to the small quantity of moisture which remains in gases, even after they have been subjected to the action of the most powerful desiccating agents (*Deut. Chem. Ges. Ber.* v. 259).

2. With *Mercury-vapour.*—A. B. v. Schrotter (*Wien Akad. Ber.* [2 Abth.], lxi. 79; *Jahresb.* 1872, 268) finds that when a few lumps of sulphur are introduced into a barometric vacuum (which is filled with mercury vapour) the tube near the surface of the mercury becomes coated with a ring of mercuric sulphide. Also when mercury and sulphur are placed together under a bell-jar the sulphur becomes blackened, showing that the jar is filled with mercury-vapour, which is absorbed by the sulphur. When iodine, mercury and sulphur are placed under a bell-jar in separate dishes, the mercury soon becomes covered with a coating of iodide, while the sulphur remains unaltered for weeks.

The use of flowers of sulphur has been recommended for removing mercury-vapour from the atmosphere of workshops in which glass mirrors are made. According to Merget, however, sulphur is not very efficacious for this purpose, and a better result is obtained by the use of bleaching powder, a small quantity of which scattered about a room infected with mercury-vapours removes the mercury in the form of calomel (*Dingl. pol. J.* cciv. 51; *Chem. Soc. J.* [2], x. 923).

3. On the action of melted sulphur on an alloy of gold and silver, see p. 576.

4. On Carbon tetrachloride. The reaction takes place readily at 130°, according to the equation:

(Gustavson, *Zeitschr. f. Chem.* [2], vii. 418).

Estimation of Sulphur.—Important observations on the precipitation of sulphur as barium sulphate, in presence of various salts, have been made by R. Fresenius (*Zeitschr. anal. Chem.* ix. 52). Barium sulphate is not, as hitherto supposed, soluble in 4,300 pts. of water, but requires for solution more than 400,000 parts. The solubility is not perceptibly increased by the presence of sodium chloride, potassium chlorate, or barium nitrate, but hydrochloric acid produces a sensible increase. Sodium chloride, mixed with the solution of a sulphate, does not give rise to any impurity in the precipitation of the sulphuric acid as barium sulphate, neither is the result in this case affected by the presence of more or less hydrochloric acid. Potassium chlorate gives rise to great contamination, but the precipitate, after ignition and cooling, may be completely purified by digestion with hydrochloric acid; as, however, barium sulphate is somewhat soluble in hydrochloric acid, the filtrates must be evaporated down to determine the quantity of barium salt dissolved in them. In presence of potassium nitrate, or sodium nitrate, the precipitated barium sulphate is very impure, whether the quantity of hydrochloric acid present, and of barium chloride added, be large or small. The only way of purifying the precipitate thus contaminated is to disintegrate it by fusion with sodium carbonate, and estimate the sulphuric acid in the aqueous solution of the fused mass. If it be desired to avoid this circuitous process, the original substance must be completely freed from nitric acid by repeated evaporation with pure hydrochloric acid, and the hydrochloric acid almost wholly driven off before proceeding to the precipitation with barium chloride. Barium nitrate likewise gives rise to contamination, but the precipitate after ignition may be purified by digestion with hydrochloric acid; regard must, however, be had to the solubility of barium chloride in hydrochloric acid. The purification of the precipitated barium sulphate by Stolla's method (digestion with solution of cupric acetate containing free acetic acid, *Jahresb.* 1863, 669), is, according to Fresenius, not to be depended on.

Volumetric method.—On account of the difficulty of obtaining a pure precipitate of barium sulphate in presence of other salts, J. Denham Smith and E. F. Teschemacher (*Chem. News* xxiv. 61, 66, 171; *Chem. Soc. J.* [2], ix. 1085) have proposed a volumetric method for the estimation of sulphur—in pyrites, for example. For this purpose they prepare a standard solution of barium chloride, and determine its strength by allowing it to flow into boiling dilute sulphuric acid, and weighing the precipitate. When precipitated in this way the barium sulphate contains scarcely any chlorine, whereas, if the precipitation be performed in the contrary way, it always contains an appreciable quantity of chlorine. The strength of the barium solution having been determined, the liquid to be tested is heated, and precipitated with it, till a filtered sample is no longer clouded by the barium solution, the sample of liquid being poured back after each experiment. The quantity of the barium solution used gives the quantity of sulphuric acid in the liquid under examination.

Glendinning a. Edger (*Chem. News* xxiv. 140) are of opinion that in applying this method to the estimation of sulphur in pyrites, errors may arise from the fact that the precipitated barium sulphate carries down with it a certain quantity of iron sulphate, and they adduce experiments tending to show that when this salt is washed out of the precipitate by water and hydrochloric acid, the sulphur in the washings reprecipitated by barium chloride, and the small precipitate of barium sulphate thus obtained added to the original precipitate, concordant results may be obtained.

The following were the results of the analyses of four samples of pyrites:—25 grains were carefully oxidised and precipitated by barium chloride in the usual way. The precipitated liquors were left in a warm place for eight hours, then filtered, and the barium sulphate was washed with boiling water and hydrochloric acid. The whole of the washings, after addition of a little barium chloride, were evaporated to dryness, and the quantities of barium sulphate obtained, amounting generally to 0.5 grain, added to the original precipitates, three of which, after ignition and weighing, were treated with about 600 grs. of strong hydrochloric acid, and allowed to

stand for twelve hours. The small quantities of sulphate dissolved by the acid were recovered, and added to their respective precipitates.

No.	Before treatment with HCl		After treatment with HCl	
	Grs. BaSO ⁴	Grs. S	Grs. BaSO ⁴	Grs. S
1	83.12	11.415	83.08	11.411

3	83.30	11.440	83.23	11.430
4	83.23	11.430	—	—

A reply to these observations is given by Smith a. Teschemacher (*Chem. News*, xxiv, 171), and a rejoinder by Glendinning a. Edger (*ibid.* 220).

Estimation of Sulphur in Coal Gas.—A. Vernon Harcourt (*ibid.* xxii, 307) determines sulphur in coal gas by causing a Bunsen flame $\frac{1}{2}$ of an inch long, and consuming $\frac{1}{2}$ cubic foot in an hour, to burn within a cylinder connected with an aspirator. The gaseous products of combustion thus drawn off pass through a series of vessels containing an ammoniacal solution of cupric oxide, which takes up the sulphurous and sulphuric acids, and oxidises the former. After about two cubic feet of gas have been consumed, the liquid is decanted into a beaker, the vessel rinsed with water, the greater part of the ammonia expelled by heat, and the sulphur precipitated by barium chloride.

(On the estimation of sulphur in Coal and Coke, see COAL (p. 347); in Coal and Organic Bodies, see MIXER (*Sill. Am. J.* [3], iv, 90; *Chem. Soc. J.* [2], x, 1114; *Jahresb.* 1872, 918). On its estimation in Pig-iron, see IRON (p. 692).

SULPHUR, CHLORIDES AND OXYCHLORIDES OF. The existence of three distinct compounds of sulphur with chlorine—viz.: *Sulphur sulphodichloride*, S²Cl², *Sulphur dichloride*, SCI², and *Sulphur tetrachloride*, SCI⁴—appears to be now placed beyond doubt by the recent researches of Huebner a. Guerout, Dalczell a. Thorpe, and Michaelis.

Thus Huebner a. Guerout (*Zeitschr. f. Chem.* 1870 [2], vi, 455) find that, if pure sulphur sulphodichloride, S²Cl² (b. p. 136.5°–137° uncor.), cooled by a good refrigerating mixture of ice and salt, is saturated with chlorine, and a current of carbonic anhydride then passed through the liquid for several hours, a product is obtained having the composition required by the formula SCI², viz.: 30.5 p.c. of sulphur and 69.3 p.c. of chlorine, the theoretical amounts being 31.07 and 68.93. Dalczell a. Thorpe (*Phil. Mag.* 1871, 309; *Jour. Chem. Soc.* [2], ix, 1163) have repeated this experiment with precisely the same result, finding 69.25 and 69.06 p.c. of chlorine in the products they obtained.

Michaelis (*Ann. Ch. Pharm.* clxx, 6) has since shown that when sulphur sulphodichloride is saturated with chlorine at about –20°, the amount of chlorine absorbed corresponds with that required to form sulphur tetrachloride, and the product actually has the composition SCI². Thus 67.5 grams S²Cl² absorbed 106 grams of chlorine, the amount required by theory being 106.5 grams; and taking the mean of two analyses, the product contained 81.59 p.c. of chlorine and 18.41 p.c. of sulphur, the theoretical numbers being 81.61 and 18.39.

Michaelis has studied the dissociation of sulphur dichloride and sulphur tetrachloride. The results which he obtained, together with the earlier observations of Carus, which are denoted by a *, are included in the following tables:

	Cl	S
SCI ²	81.61	18.39
At –22°	81.59	18.41
–15	74.21	25.79
–10	72.39	27.61
* –7	71.67	28.33
* –2	70.39	29.61
* 0.7	70.00	30.00
* 0.2	69.18	30.82

SULPHUR: CHLORIDES

Dissociation of Sulphur Dichloride.

	Cl ²	S
SCl ²	68.13	31.13
* 20	67.80	32.20
30	66.80	33.20
50	64.85	35.15
65	63.44	36.56
85	61.36	38.64
90	58.85	43.15
100	55.70	44.30
110	54.54	45.45
120	53.41	46.59
130	52.43	47.57
S ² Cl ²	52.59	47.41

From these numbers the percentage of SCl² and SCl² existing in the mixtures at the various temperatures is calculated by the aid of the formulae:

$$0.8161x + (100 - x)0.6887 = A,$$

$$0.6887x + (100 - x)0.5259 = A',$$

where x is the percentage of SCl² or SCl², and A and A' the percentage of chlorine found at the various temperatures, thus:

Dissociation of Sulphur Tetrachloride.

Temp.	Diff.	SCl ²	SCl ²	Diff.	Increase for 1°
-22°		100.00	0.00		
-15	7°	41.95	58.05	58.05	8.3
-10	5	27.62	72.38	13.32	2.6
* -7	3	21.97	78.03	5.66	1.9
* -2	5	11.93	88.07	10.04	2.0
* 0.7	2.7	8.87	91.13	3.06	1.1
* 6.2	6.5	2.43	97.57	6.44	1.1

Dissociation of Sulphur Dichloride.

Temp.	SCl ²	S ² Cl ²	Diff. for 10°	Calculated
*20°	93.45	6.55		6.00
30	87.22	12.78	6.23	12.19
50	76.41	24.59	6.41	24.57
65	66.78	33.22	5.79	33.85

90	26.48	73.52		73.52
100	19.45	80.55	7.03	80.53
110	12.85	87.65	7.10	87.54
120	5.44	94.56	6.91	94.55
130	0.00	100.00	5.44	—

The loss of chlorine by sulphur tetrachloride thus takes place with great rapidity, but the dichloride is much more stable. It will be noticed, in the case of sulphur dichloride, that the increase of decomposition is constant for equal elevations of temperature between 20° and 85°, but that it suddenly rises very quickly between 85° and 90°, from which temperature to 130° it takes place at the previous rate. The cause of this phenomenon has not been ascertained. The course of the dissociation of sulphur dichloride between 20° and 85° may be represented by the linear equation $y = 0.619x + 6.698$, and between 90° and 130° by $y = .701x + 10.43$. If in the first equation $y = 0$, x will be 10.8—that is to say, sulphur sulphodichloride, S²Cl², saturated with chlorine at 10.8°, will contain 100 p.c. of sulphur dichloride.

Michaelis has also brought forward a considerable amount of chemical evidence tending to prove the existence of sulphur tetrachloride. Thus, if chlorine is passed into sulphur sulphodichloride cooled by a mixture of ice and salt, and after some time

the refrigerating mixture is removed and displaced by ice, and sulphuric anhydride distilled into the chloride, the current of chlorine being maintained, an action takes place, only towards the close of which sulphurous anhydride is evolved. The product is a mixture of sulphurous (thionyl) and pyrosulphuric chlorides, formed in virtue of the reaction represented by the equation:

That the action does not take place in the following manner:

that is to say, that it is not the result of the reactions:

is proved by the fact, that sulphurous anhydride is evolved in small quantity only, and quite towards the end of the operation, and that the quantities of sulphurous and pyrosulphuric chlorides which are formed are in accordance with the first equation above given. The complete conversion of the S^2Cl^2 into SCl^4 , under these circumstances, is easily comprehended, although when saturated with chlorine at 0° it only contains about 9 p.c. of SCl^4 , because as fast as this latter is acted upon by the anhydride, a fresh quantity is formed by the action of the chlorine, and thus ultimately the whole of the S^2Cl^2 becomes SCl^4 .

Pure sulphur tetrachloride is acted upon by sulphuric anhydride in the following manner:

which explains the evolution of sulphurous anhydride above spoken of; a small quantity of pyrosulphuric chloride is also produced by the action of the anhydride on the sulphurous chloride. Sulphuric chlorhydrate has a similar action at 0° , and higher temperatures, hydrochloric acid being also evolved; but at temperatures below 0° a solid body of the composition $\text{S}^2\text{O}^3\text{Cl}^2$ is produced (p. 1132). Sulphur tetrachloride has no action on sulphurous anhydride.

On warming a mixture of sulphur sulphodichloride and sulphuric chlorhydrate, the following reaction occurs:

By heating phosphorous chloride with sulphur sulphodichloride to 160° , phosphoric chloride and phosphoric sulphochloride are produced:

These two substances may be easily separated by distillation, and the reaction affords a convenient method of preparing pure phosphoric sulphochloride (Michaelis, *Zeitschr. f. Chem.* [2], vii. 152).

Sulphur sulphodichloride acts readily upon aniline: sulphur is separated, and aniline hydrochloride and a resinous substance are obtained; the latter appears to be a mixture of several colouring matters, the composition of which has not, however, been ascertained (Claus, *J. pr. Chem.* [2], iii. 256). When sulphur sulphodichloride is added to a solution of aniline in carbon bisulphide, the following reaction occurs:

If more than 1 mol. of sulphur chloride is employed, the sulphocarbaniide is converted into phenyl isosulphocyanate (phenylic mustard-oil) and triphenylguanidine hydrochloride, thus (Claus & Krall, *ibid.* 240):

the reaction being precisely similar to that which Hofmann has shown to occur with iodine.

OXYCHLORIDES OF SULPHUR.

Sulphurous Chloride, SOCl^2 . According to Michaelis (*Ann. Ch. Pharm.* clxx. 20), this compound is readily prepared by the action of sulphuric anhydride on sulphur tetrachloride:

It is easily separated by distillation from the small quantity of pyrochloride which is formed, and about 80 p.c. of the amount which theory indicates may be obtained in this way.

Sulphuric Chloride, SO^2Cl^2 . Michaelis (*Zeitschr. f. Chem.* [2], vii. 149) has failed to obtain this compound by the action of phosphoric chloride on sulphuric anhydride, sulphuric chlorhydrate, and lead sulphate (v. 578), but he succeeded in preparing it by Regnault's method.

It is produced by heating sulphuric anhydride with boron chloride in sealed tubes to 120° for eight hours (Gustavson, *Deut. Chem. Ges. Ber.* vi. 9):

Gustavson did not succeed, however, in obtaining sulphuric bromide by employing boron bromide: the products in this case were sulphurous anhydride, bromine, and the compound of boric and sulphuric anhydrides.

Sulphurous chloride may be prepared by passing a mixture of sulphurous anhydride and chlorine over purified charcoal, or into glacial acetic acid. In the latter case, it is separated from the acid by distillation.

Sulphurous chloride is gradually acted upon by phosphoric chloride at the ordinary temperature (Michaelis):

Benzene is not attacked by sulphurous chloride even at the boiling point of the mixture, but on heating in sealed tubes to 150° the following reaction occurs:

Similarly, phenol is converted into monochlorophenol, but the action takes place readily at ordinary temperatures (Dubois, *Zeitschr. f. Chem.* [2], ii. 705).

Pyrosulphuric Chloride, $\text{S}^2\text{O}^2\text{Cl}^2$ or $\text{ClO}^2\text{S}-\text{O}-\text{SO}^2\text{Cl}$. This compound is produced on warming together phosphoric chloride and sulphuric anhydride:

and by the action of phosphoric chloride on sulphuric chlorhydrate (Michaelis, *Zeitschr. f. Chem.* [2], vii. 149):

It is also formed by the action of sulphuric anhydride on sulphur sulphodichloride and sulphur tetrachloride (Michaelis), and on silicon tetrachloride (Gustavson), and by heating sulphuric anhydride with phosphoric oxychloride to 160° (Michaelis):

Pyrosulphuric chloride is a colourless, oily liquid of sp. gr. 1.819 at 18°, boiling at 146° (corr.) (Michaelis). In contact with water it decomposes slowly and noiselessly, and is thus distinguished from sulphuric chlorhydrate, which is rapidly decomposed with almost explosive violence when thrown into water. When heated above its boiling point, it is resolved into chlorine and sulphurous and sulphuric anhydrides (Armstrong, *Proc. Roy. Soc.* xviii. 511):

When submitted to the action of phosphoric chloride, it furnishes chlorine, sulphurous anhydride, and phosphoric oxychloride (Armstrong; Michaelis):

The hydrocarbons of the benzene series and their derivatives, the phenols, &c., are readily acted upon by pyrosulphuric chloride; the mode of action is represented by the following general equations:

Chlorine, however, appears never to be evolved as such, but produces chlorinated compounds: phenol, for example, yields a mixture of chlorophenol and chlorophenol-sulphonic acids. The extent to which the reactions above formulated occur is found to vary with the conditions of experiment and the nature of the substance acted upon. Benzene, for example, yields all the possible products, whilst with the crystalline dibromobenzene the reaction is chiefly that represented by the first equation (Armstrong a. Pike, *Chem. News*, xlix. 283).

Sulphur Oxytetrachloride, $\text{S}^2\text{O}^2\text{Cl}^4$ or $\text{ClO}^2\text{S}-\text{O}-\text{SOCl}_2$. To prepare this compound, which was first obtained by Millon by the action of moist chlorine on chloride of sulphur saturated with chlorine (*Ann. Ch. Phys.* [3], xlix. 237), a mixture of 1 mol. of sulphur sulphodichloride and 2 mols. of sulphuric chlorhydrate is introduced into

a capacious flask, surrounded by a mixture of ice and salt, and dry chlorine passed in through a wide tube. A considerable evolution of gas soon sets in, and a solid substance separates; the crust is broken from time to time with a glass rod, and when the whole is converted into solid, the flask is removed from the refrigerating mixture, and the current of chlorine continued until the reddish mass becomes colourless. This is facilitated by frequent shaking. The excess of chlorine is then displaced by a current of dry carbonic anhydride, and the product afterwards transferred to stoppered bottles. Any required quantity of the substance may in this way be prepared with the greatest readiness (Michaelis, *Ann. Ch. Pharm.* clxx, 22).

Sulphur oxytetrachloride is a white crystalline substance when pure, but is usually coloured yellow by adhering chlorine; it then closely resembles phosphoric chloride in appearance. It decomposes violently in contact with water, sulphurous, sulphuric, and hydrochloric acids being produced and sulphur separated; when a mixture of ice and water is employed, however, no sulphur separates:

When exposed over water under a shade it gradually deliquesces, and chlorine, sulphurous anhydride, and hydrochloric acid are evolved; the liquid is a mixture of sulphurous and pyrosulphuric chlorides. When heated to 57° it melts with evolution of chlorine and sulphurous anhydride, but a portion sublimes in fine white needles; if the heating be continued, a liquid product is obtained, consisting of sulphurous and pyrosulphuric chlorides:

It is changed, after long keeping in sealed tubes, into a yellow liquid; this boils at 73°, and appears to be a mixture of sulphurous and sulphuric chlorides:

Sulphuric acid decomposes sulphur oxytetrachloride as follows:

Sulphur oxytetrachloride acts most violently upon carbon bisulphide:

Alcohol also acts violently upon the chloride, ethyl chloride and sulphurous acid being evolved, but the nature of the remaining products has not been ascertained.

Sulphuric Chlorhydrate, $SO^2HCl = SO^2\begin{smallmatrix} OH \\ Cl \end{smallmatrix}$. The product obtained by the action of 1 mol. phosphoric chloride on 1 mol. sulphuric acid is a mixture of pyrosulphuric chloride and sulphuric chlorhydrate. Pure sulphuric chlorhydrate can be obtained by using the proportions recommended by Williams (1st *Suppl.* 1069), and by the action of phosphoric oxychloride on sulphuric acid:

Also by warming a mixture of phosphorous chloride and sulphuric acid (Michaelis, *Zeitschrift. f. Chem.* [2], vii. 150):

It is advantageously prepared by slowly adding 1 mol. of phosphorous chloride to 3 mols. sulphuric through which a current of dry chlorine is passed; the flask containing the acid should be surrounded by cold water (Michaelis, *Ann. Ch. Pharm.* clxx, 24).

Sulphuric chlorhydrate is a colourless liquid, of sp. gr. 1.776 at 18°; it boils at 158.4 (corr.) (Michaelis).

The action of sulphuric chlorhydrate on a number of hydrocarbons and derivatives of hydrocarbons of the benzene series has been examined by Armstrong and by Armstrong a. Pike (*Chem. Soc. J.* [2], ix. 173; *Chem. News*, xxix. 283). The action may take place as represented by the following equations:

It varies, however, both with the nature of the substance acted upon and the conditions of experiment. Thus when the chloride is added to well-cooled toluene, the product consists almost entirely of toluene-sulphonic acid; but if the temperature is allowed to rise during the reaction, less sulphonic acid is produced, and a considerable quantity of toluene-sulphonic chloride and toluene sulphone, $(C^6H^5)SO^2$, is obtained. When the toluene is added to the chloride without cooling, the proportion of the two latter products is still greater.

H. E. A.

1134 SULPHUR: OXIDES AND OXYGEN-ACIDS.

SULPHUR, OXIDES AND OXYGEN-ACIDS OF. I. Sulphurous Oxide, Acid, and Salts: On the tension of sulphurous oxide at different temperatures, and its deviation from Boyle's law, see GASES (p. 547).

On its reaction with *phosphorous chloride*, see pp. 959, 960.

On its combination with *tricalcio phosphate*, see PHOSPHATES (p. 971); also *Chem. Soc. J.* [2], x. 39.

The action of sulphurous acid on certain metals has been studied by P. Schweizer (*Chem. News*, xxiii. 293). With *zinc* the products are hyposulphurous and trithionie acids and zinc sulphite, with separation of sulphur (compare 1st Suppl. 1063). With *cadmium* the products are sulphate, thiosulphate, dithionate, and sulphide, together with free sulphuric acid and sulphur:

According to the last equation, sulphur in the nascent state should have the power of converting cadmium sulphite into cadmium sulphide and sulphuric anhydride. The action on *nickel* is similar, the first products being sulphite and thiosulphate of nickel, with a little free sulphur, afterwards sulphide and sulphate. On *aluminium* at ordinary temperatures and on *magnesium* at higher temperatures, sulphurous acid acts according to the following independent equations:

On the action of sulphurous acid on *platinic chloride*, see PLATINUM (p. 985).

On the use of sulphurous acid in Bleaching, see F. Froesenius (*Chem. Centr.* 1871, 174; *Chem. Soc. J.* [2], ix. 452); in the Sugar manufacture: P. Schulze (*Dingl. pol. J.* cc. 231; *Jahresh. f. Chem.* 1871, 1082); in Brewing: Boanos (*Dingl. pol. J.* cxvii. 268; *Jahresh.* 1870, 1209).

METALLIC SULPHITES. Spontaneous Decomposition.—C. Saint Pierre (*Compt. rend.* lxii. 460; lxxiii. 749) finds that a dilute solution of acid potassium sulphite (prepared by treating 30 grams of carbonate with sulphurous acid, and diluting to 200 c.c.), heated in sealed tubes to 100°, and then left to itself for a long time (4 years), is resolved into sulphate, trithionic acid, and free sulphur:

A solution of *acid lead sulphite* kept for somewhat more than a year in sealed tubes at the atmospheric temperature was found to be completely decomposed, the whole of the lead being precipitated as sulphate, together with a little sulphur, while the solution contained free sulphuric acid, and another acid which gave a precipitate when warmed with a solution of cupric sulphate. From a solution of *acid barium sulphite* enclosed in sealed glass tubes, the whole of the barium was precipitated as sulphate after 10–12 hours heating in the water-bath. The solution still contained sulphurous acid, together with sulphuric acid, and an acid which formed black precipitates with mercury and silver salts. *Liquid sulphurous oxide* and the *concentrated aqueous solution* enclosed in glass tubes underwent no alteration either when heated in the water-bath for a month, or when kept at the atmospheric temperature for three years (Saint Pierre, *Compt. rend.* lxxiv. 52). At 170°–200°, however, aqueous sulphurous acid is resolved into sulphuric acid and free sulphur (Geitner, *Ann. Ch. Pharm.* cxxiv. 128; cxxix. 350; *Jahresh.* 1862, 69; 1864, 140).

Copper Sulphites.—These salts have been examined by N. Svenssen (*Deut. Chem. Ges. Ber.* iv. 713). The ordinary red salt is, as stated by Rammelsberg, a cuprous-cupric sulphite, $\text{Cu}^2\text{SO}^3.\text{CuSO}^3 + 6\text{H}^2\text{O}$. The simple cuprous sulphite, Cu^2SO^3 , described by Rogojaki (v. 544), Svenssen was unable to obtain. The following double salts were prepared:

Indium Sulphite, $2\text{In}^2\text{O}^3 \cdot 3\text{SO}^2 + 8\text{H}^2\text{O}$ (p. 680).

Magnesium Sulphite.—According to G. Archbold (*Pharm. J. Trans.* [3], ii. 844), the salt obtained by passing sulphurous oxide into water in which magnesium carbonate is suspended, crystallises in tetrahedrons, has the composition $\text{Mg}(\text{SO}^2)^2 + 6\text{H}^2\text{O}$, and gives off all its water at 100° (compare v. 546 and *Gmelin's Handbook*, iii. 235).

On the Sulphites of Platinum-bases, see pp. 993, 995, 996.

Potassium Sulphite.—On the spontaneous decomposition of acid potassium sulphite, see p. 1134.

The action of potassium sulphite on compounds containing the group CCl^3 has been studied by Rathke (*Ann. Ch. Pharm.* clxi. 140). 1. When *trichloroformenesulphonic chloride*, $\text{CCl}^3 \cdot \text{SO}^2\text{Cl}$, is treated with a solution of neutral solution of potassium sulphite, the mixture becomes hot, sulphurous oxide is given off, and the following reaction takes place:

The easily decomposed potassium salt of the acid $\text{CCl}^3 \cdot \text{SO}^2\text{H}$, formed on neutralisation, cannot be separated out, but the presence of the acid is demonstrated by its peculiar penetrating odour, and by the immediate precipitation of trichlorosulphonic chloride on passing chlorine through the mixture. On boiling the solution of the potassium salt, it is converted into Kolbe's dichloroformenesulphonate of potassium:

Potassium trichloroformenesulphonate, $\text{CCl}^3 \cdot \text{SO}^2\text{K}$, mixed in solution with potassium sulphite, is first converted into the dichloroformenesulphonate, thus:

and then at temperatures above 100° into potassium formenedisulphonate (methionate), some potassium dithionate being also formed.

2. *Chloropicrin*, CCl^3NO^2 , digested at a gentle heat with a solution of potassium sulphite, soon dissolves, producing potassium nitroformenedisulphonate, $\text{CH}(\text{NO}^2)(\text{SO}^2\text{K})^2$. This salt dissolves easily in hot, slowly in cold water; crystallises in spheroidal groups of microscopic plates, bears a tolerably high temperature without change, but detonates rather smartly at a stronger heat; gives precipitates with baryta-water and basic lead acetate, none with barium chloride, neutral lead acetate, silver nitrate, or mercurous nitrate.

3. The reactions of potassium sulphite with *trichloroacetic acid* and *chloral hydrate* have already been described (pp. 10, 309).

Silver Sulphites.—The following double sulphites of silver have been prepared by Stenksen (*loc. cit.*):

Sodium Sulphites.—According to Schultz-Sellack (*J. pr. Chem.* [2], ii. 459), neutral sodium sulphite, Na^2SO^3 , crystallises with 7 mols. H^2O ; the deca-hydrated salt described by Muspratt (v. 550), Schultz-Sellack was unable to obtain. A supersaturated solution likewise yields the salt $\text{Na}^2\text{SO}^3 + 7\text{H}^2\text{O}$. Sodium sulphite has, like the sulphate, a maximum of solubility, and separates from warm solutions in the anhydrous state, as observed by Rammelsberg. This anhydrous salt is perfectly unalterable in the air, and when moistened with water cakes together, and is converted into the hydrate. From a solution containing a large excess of caustic soda it separates by evaporation in a vacuum at ordinary temperatures, in somewhat more distinct crystals. The *anhydrosulphite*, $\text{Na}^2\text{SO}^3 \cdot \text{SO}^2$, formed by supersaturating a concentrated solution of sodium carbonate with sulphurous acid, crystallises on cooling, and gradually gives off sulphurous oxide on exposure to the air.

II. *Sulphuric Oxide, Acid, and Salts*.—SULPHURIC OXIDE or ANHYDRIDE, SO^3 . The existence of two modifications of this body, first noticed by Marignac (v. 569) has been confirmed by Schultz-Sellack (*Pogg. Ann.* cxxxix. 480). *α-Sulphuric oxide*, formed on cooling the liquid oxide, solidifies at $+16^\circ$ in long colourless prisms which melt at the same temperature; it boils at 46° ; vapour-tension at 20° , about 200 mm. *β-Sulphuric oxide* is produced from the *α*-modification at temperatures below 25° , above 27° the transformation does not go on. It forms extremely fine white needles; at temperatures above 50° it gradually liquefies and passes into the first modification; at ordinary temperatures it gradually forms vapours which have the constitution of the vapour of the first modification, and after remaining for a week in

a vacuum, at 20° , have a tension of 30–40² mm. The vapour, both of the solid and of the liquid oxide, exhibits the normal density, viz. 2.74 to 2.76 (calc. for $\text{SO}^2 = 2.76$). The liquid oxide undergoes very great expansion by heat, its mean coefficient of expansion between 25° and 45° being 0.0027 for 1° , that is to say, more than two-thirds as great as that of gases. The two modifications also differ greatly in their relations to solvents. Liquid sulphuric oxide mixes in all proportions with hydrogen sulphate, H^2SO^4 ; the β -oxide dissolves in sulphuric acid with extreme slowness, and gradually separates from a mixture of 10 pts. SO^2 and 1–2 pts. H^2SO^4 . With a larger proportion of the acid, no solid oxide separates, even on cooling to a low temperature; if the proportion of acid, H^2SO^4 , amounts to 5 pts. for 10 pts. of oxide, the mixture may deposit crystals of pyrosulphuric acid, $\text{H}^2\text{S}^2\text{O}^7$ or $\text{H}^2\text{SO}^4.\text{SO}^2$.

Liquid sulphuric oxide likewise mixes in all proportions with sulphurous oxide; if the latter is in excess, the mixture does not deposit anything solid, even when cooled to a low temperature. A mixture of equal parts of the two deposits on cooling β -sulphuric oxide, which redissolves at ordinary temperatures; if, on the other hand, the sulphuric oxide is in excess, part of the mixture solidifies even at ordinary temperatures. Sulphuric and sulphurous oxides do not appear to form a definite compound, as supposed by H. Rose (*Pogg. Ann.* xxxix. 173); nevertheless, the existence of a strong attraction between them may be inferred from the raising of the boiling point of the mixture. A mixture of the two oxides in equal parts boils at $+5^{\circ}$.

Carbon Sulphide mixes perfectly with liquid sulphuric oxide at 30° ; at 15° each of these liquids takes up only about $\frac{1}{2}$ of the other. A mixture of the two in equal parts boils at 34° . They act chemically on one another, especially in presence of small quantities of sulphuric acid, the mixture after a while depositing a brown viscid mass. (Compare 1st. *Suppl.* p. 1067.)

Reactions.—Selenium exposed to the vapour of sulphuric oxide at ordinary temperatures is converted, first into a pasty mass, then into a yellow granular powder, SeSO^2 , which, when gently heated, gives off sulphurous oxide and leaves selenium; it dissolves with yellow colour in sulphuric acid, the selenium being precipitated on dilution with water. Tellurium is almost completely oxidised by sulphuric oxide even at ordinary temperatures. Iodine exposed to the vapour of sulphuric oxide forms laminar crystals having nearly the composition I^2SO^2 . Partial oxidation takes place, however, perhaps to periodic acid, and sulphurous oxide is evolved.

On the reaction of sulphuric oxide with phosphorous chloride, see p. 960.

The chlorides of the alkali-metals exposed to the long-continued action of sulphuric oxide vapour are converted into granulo-crystalline masses, having the composition $\text{NaCl}(\text{SO}^2)^4$ and $\text{KCl}(\text{SO}^2)^4$. With silver chloride, a compound is formed having nearly the composition $\text{AgCl}(\text{SO}^2)^4$. Barium chloride yields the compound $\text{BaCl}^2(\text{SO}^2)^3$, which, when heated, first gives off SO^2 , then chlorine and SO^2 , leaving barium sulphate.

Sulphuric oxide is likewise absorbed by metallic fluorides, bromides and iodides, but in the two latter cases with decomposition, and separation of bromine or iodine. Mercuric cyanide absorbs sulphuric oxide, but likewise with partial decomposition. Potassium nitride appears to form with it the compound KNOSO^4 , which, however, is more easily obtained by the action of liquid sulphurous oxide on potassium nitrate, with careful exclusion of water. The action of sulphuric oxide on saltpetre does not yield any compound analogous to the lead-chamber crystals, HNO^2SO^4 .

When vapour of sulphuric oxide is passed slowly and with frequent agitation into strong nitric acid well cooled by water or ice, a thickish oily mass is obtained, which at a certain degree of concentration either deposits crystals or crystallises altogether. On dissolving this crystalline product in gently warmed dilute nitric acid, and draining the crystals which separate on cooling on a porous tile, they are obtained colourless and dry. Their analysis gives numbers leading to the empirical formula, $48\text{O}^2.\text{N}^2\text{O}^3.3\text{H}^2\text{O}$; whence may be deduced the rational formula, $\text{N}^2\text{O}^4.\text{SO}^2 + 3\text{SO}^2.\text{H}^2$. The crystals are very deliquescent, and decompose when heated, giving off brown fumes and yielding a sublimate which exhibits the properties of the compound $\text{N}^2\text{O}^4.\text{SO}^2$ (R. Weber, *Pogg. Ann.* cxliii. 602).

On Boric Anhydrosulphate, see Boxon (p. 208).

Action of Water on the Lead-Chamber crystals.—Rammelsberg (*Deut. Chem. Ges. Ber.* v. 310) reports experiments by Philipp, from which it appears that the products of this reaction are nitrogen dioxide, nitric acid and nitrous acid. The crystals contain 11.02 p.c. nitrogen; the decomposition by water gave 11.76 p.c.; viz. 2.67 as nitrogen dioxide, 1.65 as nitric acid, and 7.54 as nitrous acid. The nitrogen dioxide and nitric acid are formed by the action of water on the nitrous acid (in which form probably the whole of the nitrogen is present in the crystals). The crystals decomposed by a solution of potassium iodide yield 9 p.c. nitrogen—that is to say, nearly 3 $\frac{1}{2}$ times as much as when they are decomposed by water.

On the reaction of sulphuric oxide and fuming sulphuric acid with boric oxide, see BORON (p. 208).

SULPHURIC ACID, H_2SO_4 . *Occurrence in Nature.*—In several localities near the Gulf of Mexico, small stagnant pools of water are found containing free sulphuric acid (1·529 gram in a litre). These waters likewise contain a large quantity of aluminium sulphate, together with iron sulphate, and most of them give off bubbles of hydrogen sulphide, marsh gas, and carbon dioxide. A petroleum spring occurs in the neighbourhood (J. W. Mallet, *Chem. News*, xxvi. 117).

On the Formation of Sulphuric acid in the Animal body, see E. Salkowski (*Deut. Chem. Ges. Ber.* v. 637; *Chem. Soc. J.* [2], x. 1033).

Manufacture.—On the Preparation of Sulphuric acid by the Roasting of Sulphuretted ores, see Hasenclever a. Helbig (*Dingl. pol. J.* cxix. 284; *Chem. Centr.* 1871, 267; *Jahresb. f. Chem.* 1871, 981).

On the Concentration of Sulphuric acid, Stoddart (*Chem. News*, xxiii. 167; *Dingl. cc.* 419; *Jahresb.* 1010); Bode (*Dingl. cc.* 45; *Chem. News*, xxiv. 82; *Jahresb.* 1871, 1010); Galletly (*Chem. News*, xxiv. 106; *Dingl. cc.* 538; *Jahresb.* 1871, 1010); Hasenclever (*Deut. Chem. Ges. Ber.* v. 502; *Dingl. ccv.* 125; *Jahresb.* 1872, 973; *Chem. News*, xxvi. 174; *Chem. Soc. J.* [2], x. 929); De Hemptinne (*Dingl. ccv.* 419; *ccvi.* 155; *Jahresb.* 1872, 973).

On the recovery of Nitrous acid in Sulphuric acid works by the use of Glover's Towers, see G. Lunge (*Dingl. cc.* 341; *ccii.* 532; *Chem. Centr.* 1871, 618; *Jahresb.* 1871, 1011, 1014); F. Bode (*Dingl. ccii.* 448; *Jahresb.* 1871, 1013; *Chem. Soc. J.* [2], x. 1013).

On the Heat of Combination of Sulphuric acid with Water, see p. 633 of this volume; also Thomsen (*Deut. Chem. Ges. Ber.* iii. 496; *Jahresb.* 1870, 127–129).

Electrolysis.—According to H. Highton (*Chem. News*, xxvi. 117), when dilute sulphuric acid is electrolysed, with zinc for the positive and charcoal for the negative electrode, hydrogen sulphide is evolved at the latter. That this gas does not proceed from pyrites mixed with the carbon is shown by the fact that its evolution ceases as soon as the circuit is broken.

On the Reduction of Sulphuric acid to Hydrogen Sulphide by the action of *Nascent Hydrogen*, see p. 658.

On the action of Sulphuric acid on Alcohol and Ether at high temperatures, see ETHYL ALCOHOL (p. 473).

On the Electrolysis of sulphates, p. 460.

Antimonious Sulphate, $Sb_2(SO_4)_3$, is obtained by evaporating a solution of antimonious oxide in moderately concentrated sulphuric acid, in long needles having a silky lustre. It is permanent in dry air, is decomposed by water, and gives off sulphuric oxide at a red heat (Schultz-Sellack, *Deut. Chem. Ges. Ber.* iv. 13).

Barium Sulphate, $BaSO_4$.—H. Struve (*Zeitschr. anal. Chem.* ix. 34) corroborates the fact observed by Schultz-Sellack (*1st Suppl.* 1070–1073) that the sulphates of barium, calcium, strontium, and lead dissolve in strong sulphuric acid, and separate from the solution in crystals on evaporation; he gives the following Table of solubilities:

	100 pts. of strong sulphuric acid dissolve	100 pts. of Nordhausen sulphuric acid dissolve
$BaSO_4$	5·69 pts.	15·80 pts.
$SrSO_4$	5·68	9·77
$CaSO_4$	2·03	10·17
$PbSO_4$	0·13	4·19

On the solubility of barium sulphate in water and hydrochloric acid, and on its precipitation in presence of other salts, see p. 1128.

Bismuth Sulphates.—According to Schultz-Sellack (*Deut. Chem. Ges. Ber.* iv. 13), the normal salt, $\text{Bi}(\text{SO}_4)^3$, is easily obtained by evaporating a solution of bismuth oxide in moderately strong sulphuric acid, and forms slender needles which may be heated nearly to redness without decomposition. According to A. Leist, on the other hand (*Ann. Ch. Pharm.* clx. 29), the salt formed by dissolving bismuth oxide in sulphuric acid is not a neutral, but a mixture of an acid salt, $\text{Bi}^2\text{O}^3 \cdot 4\text{SO}^3 + 7\text{H}^2\text{O}$ (or $+ 9\text{H}^2\text{O}$, according to the concentration of the sulphuric acid, from which the salt has crystallised) = $\text{BiH}(\text{SO}_4)^2 + 3\text{H}^2\text{O}$, with a basic salt, $\text{Bi}^2\text{O}^3 \cdot 2\text{SO}^3 + 2\text{H}^2\text{O}$, agreeing with Heintz's sesquibasic sulphate (v. 584), excepting that it contains 1 mol. water less. The acid salt is obtained by dissolving bismuth oxide in moderately dilute sulphuric acid (1 pt. H^2SO^4 to 2 or 3 pts. H^2O), redissolving the basic salt which separates in a large quantity of sulphuric acid (about 1 pound of strong sulphuric acid to 15 grams of bismuth oxide), then filtering and evaporating. The acid salt then separates in long shining needles which may be freed from mother-liquor by spreading them on a tile and pressing them between bibulous paper. It is insoluble in water, but dissolves in acids, especially in hydrochloric and nitric acids. When washed for several days with hot water, and then carefully dried by pressure for a week between bibulous paper, it was converted into a salt having the composition $4\text{Bi}^2\text{O}^3 \cdot 3\text{SO}^3 + 15\text{H}^2\text{O}$. The basic salt, $\text{Bi}^2\text{O}^3 \cdot 2\text{SO}^3 + 2\text{H}^2\text{O}$, is obtained by dissolving bismuth oxide in sulphuric acid diluted as above, filtering from separated salt, and evaporating. The crystals are likewise needle-shaped, but not so long as those of the acid salt (Leist).

Cadmium Sulphate.—This salt, subjected for several hours to the action of a stream of ammonia gas, falls to powder and is converted into the ammonio-salt, $\text{CdSO}_4 \cdot 6\text{NH}_3$, the ammonia in which exhibits the following tensions:

Temperature Tension in millimeters of mercury	48.5°	51.5°	100°	100°	100°	100°	100°	100°
	368	439	1374	1364	1366	1364	1361	1365

The compound left after heating to 100° is $\text{CdSO}_4 \cdot 2\text{NH}_3$. These ammonia-compounds, like all others of the same class in the pulverulent form, absorb ammonia mechanically like charcoal, the tension of the gas at any given temperature being variable up to the point at which the salt retains only combined ammonia (Isambert, *Compt. rend.* lxx. 456). Compare 1st Suppl. p. 426.

Cerium Sulphates. See CERIUM (p. 275).

Glucinum Sulphate, $\text{GSO}^4 + 4\text{H}^2\text{O}$, crystallises in the quadratic system. Axes $a : c = 1 : 0.9461$. Observed forms, 011 (110), or $\text{P}^\infty \cdot \infty \text{P}$. Sp. gr. of the crystals = 1.725 (Topsøe, *Wien. Acad. Ber.* [2 abth.] lxxvi. 5).

Gold Sulphates (p. 576).

Iron Sulphates.—H. Rheinock (*Dingl. pol. J.* cccii. 268; *Chem. Soc. J.* [2], x. 225) infers from experiments of his own that ammonio-ferrous sulphate and potassio-ferrous sulphate crystallise, not with 6 mols. water, as commonly supposed, but with 5 mols. According to E. Fleischer, on the other hand (*J. pr. Chem.* [2], v. 437; *Chem. Soc. J.* [2], x. 1079), the ammonio-ferrous salt has the formula commonly assigned to it, viz.: $\text{Fe}(\text{NH}_4)(\text{SO}_4)^2 + 6\text{H}^2\text{O}$.

Lead Sulphate, PbSO^4 .—On the solubility of this salt in strong sulphuric acid, see p. 1137. On its solubility in various salts of organic acids in presence of alcohol, see F. H. Storer (*Chem. News*, xxi. 17; *Jahresb.* 1870, 356).

Magnesium Sulphates.—**Ammonium-magnesium sulphate,** $(\text{NH}_4)^2\text{SO}_4 \cdot \text{MgSO}_4 + 6\text{H}^2\text{O}$, has been found by O. Popp (*Ann. Ch. Pharm.*, Suppl. viii. 1) in the boric acid lagunes of Tuscany, especially in those at Sasso and Acquaviva, which are poorest in boric acid. In the salt from these two localities, not purified by recrystallisation, the magnesia is replaced in variable proportions by manganese and ferrous oxides, and lime appears also to be present as an amorphous constituent. The mother-liquors which remain after the crystallisation of the boric acid contain small quantities of potassium-magnesium sulphate. Popp designates all the isomorphous double sulphates of the magnesia group occurring in the fumaroles of Tuscany as 'Carbolites.'

A solution of 1 mol. potassium chloride and 1 mol. magnesium sulphate deposits, on evaporation, the double salt, $\text{K}^2\text{SO}_4 \cdot \text{MgSO}_4 + 6\text{H}^2\text{O}$, which, when treated with a quantity of water not sufficient to dissolve it completely, leaves a residue of pure potassium sulphate, while the solution deposits first the double salt above mentioned, and then the salt $\text{K}^2\text{SO}_4 \cdot 2\text{MgSO}_4 + 14\text{H}^2\text{O}$. The mother-liquor decanted from the first salt yields, by further concentration, a crop of crystals which, when dried upon a tile, have the composition $2\text{K}^2\text{SO}_4 \cdot 4\text{KCl} \cdot \text{MgCl}_2 + 7\text{H}^2\text{O}$ or $\text{K}^2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 4\text{KCl} + 7\text{H}^2\text{O}$.

The following crystallisations consist chiefly of potassium-magnesium chloride, and the last mother-liquors contain almost pure magnesium chloride.

Molybdenum Sulphates.—*Neutral molybdic sulphate*, $(\text{MoO})^2\text{SO}^4$, separates, according to Schultz-Sellack (*Deut. Chem. Ges. Ber.* iv, 13), from a solution of the trioxide in moderately strong sulphuric acid, in colourless shining crystals which deliquesce on exposure to the air, and turn blue in consequence of the reducing action of particles of dust. When heated they easily decompose, and give off sulphuric oxide. The aqueous solution dries up to a horny mass. The salt, $\text{Mo}^2(\text{SO}^4)^2$, described by Anderson (v. 605), Schultz-Sellack was unable to obtain.

Platinum Sulphates, Ammoniacal (pp. 994–1003).

Potassium Sulphate, K^2SO^4 .—H. Grüneberg (*Chem. Centr.* 1870, 623) prepares this salt by decomposing native potassium-magnesium sulphate (schönite) with potassium chloride. The reaction would proceed according to the equation:

were it not that the carnallite (or magnesium chloride) produced interferes with the complete action of the salts on one another. The saturated solution (27° B.) of 2 mols. schönite is added at the boiling heat to 3 mols. of finely powdered crystallised potassium chloride. The latter is quickly converted into sulphate, but as soon as the temperature of the solution falls below 40°, chloride of potassium again separates out. To prevent this, the lye must be decanted from the potassium sulphate while at 40°. On evaporating this liquid, potassium sulphate crystallises out first, then schönite, and lastly carnallite. The potassium sulphate may be easily brought to 95 p.c. by centrifugalising and covering it with a small quantity of water.

Schönite may also be decomposed by niterating it several times with a cold saturated solution of pure potassium chloride (21° B.)

To purify the crude commercial potassium sulphate (*plate sulphate of potash*), which usually has the composition $3\text{K}^2\text{SO}^4 \cdot \text{Na}^2\text{SO}^4$ (vi. 609), Sonstadt (*Chem. News*, xxvi. 195) boils the aqueous solution with potassium chloride. The hot solution on cooling deposits pure chloride of potassium, the sodium chloride remaining dissolved. This 'plate sulphate' does not appear to be a true double salt, as its composition is not constant. A well-crystallised sample was found by J. Mahony (*ibid.* xxii. 217) to contain 77.60 p.c. K^2SO^4 (calc. 78.56).

On the reaction of potassium sulphate with *gypsum*, see p. 589.

Silver Sulphate.—On the reactions of this salt with *iodoform*, *chloroacetic acid*, *chlorobenzoic acid*, and *ethyl iodide*, see Kämmerer (*Deut. Chem. Ges. Ber.* iv, 219; *Jahresb.* 1871, 654; *Chem. Soc. J.* [2], 552).

Sodium Sulphate, Na^2SO^4 .—*Crystallisation.*—According to Schultz-Sellack (*J. pr. Chem.* [2], ii. 459) a solution of this salt mixed with a large quantity of caustic soda deposits it at ordinary temperatures in the anhydrous state.

The spontaneous crystallisation of sodium sulphate from supersaturated solutions has been studied by De Coppet (*Bull. Soc. Chim.* [2], xvii. 146–155). His experiments confirm the statement of Loewel (v. 613), that the crystallising temperature of the heptahydrate, $\text{Na}^2\text{SO}^4 \cdot 7\text{H}^2\text{O}$, is for the most part higher as the solution is more concentrated; there is, however, no definite relation between the concentration and the depression of the crystallising point below the temperature of normal saturation. For a solution of given strength the crystallising point may vary by several degrees. According to existing observations the lowering of the crystallising temperature amounts to at least 7°, and mostly to about 12° for solutions containing from 20 to 35 pts. of anhydrous salt to 100 pts. water. With regard to the crystallisation of the decahydrate, $\text{Na}^2\text{SO}^4 \cdot 10\text{H}^2\text{O}$, De Coppet infers from his experiments that it is higher when the solution is quickly cooled. The presence of crystals of the heptahydrate exerts no perceptible influence on the crystallising temperature of the decahydrate. The influence of concentration is likewise almost imperceptible. At all events, the crystallisation of the decahydrate does not always take place exactly at -8° to -7° , as stated by Violette and Baumhauer. The point at which crystallisation begins is not regulated by any definite law. The first crystal forms sometimes on the side of the vessel, sometimes at the surface or in the interior of the liquid. In general a saline solution crystallises more readily the larger its quantity.

From his numerous observations on the freezing of saline solutions (pp. 1068–1071) De Coppet infers that the 'new hydrate' of sodium sulphate said by Tomlinson (*Proc. Roy. Soc.* xx. 109; *Chem. Soc. J.* [2], 4, 284) to crystallise at or below -3.3° , and by Violette (*Études sur la Crystallisation*, Paris, 1867) at -4° , is nothing but a mixture of ice and the hydrate, $\text{Na}^2\text{SO}^4 \cdot 7\text{H}^2\text{O}$. According to De Coppet, sodium sulphate is at present known in four states, viz.: two modifications of the anhydrous salt, one separating below and the other above 33° , and the two hydrates with 7 and 10 mols.

H²O (*Compt. rend.* lxxiii. 1324; *Chem. News*, xxiii. 266; xxv. 102; *Chem. Soc. J.* [2], x. 284, 465). See also Liversidge (*Proc. Roy. Soc.* xx. 497-507).

On the *Specific Heat*, and *Density*, and *Expansion-coefficient* of aqueous sodium sulphate, see *HEAT* (pp. 599, 601, 603).

Strontium Sulphate, CrSO⁴.—On the solubility of this salt in sulphuric acid, see p. 1137.

Uranium Sulphates.—Normal uranic sulphate, (UO²)²SO⁴, [U = 240], separates on evaporation from solution in strong sulphuric acid, in honey-yellow, non-fluorescent crystals. It is not decomposed at a low red heat. It dissolves abundantly, though slowly, in water, and gradually absorbs water from the air. By dissolving it in not quite concentrated sulphuric acid and slowly evaporating the solution in an open dish at 200°, an acid sulphate, H²(UO²)(SO⁴)², analogous in composition to the lead-chamber crystals, is obtained in fluorescent crystals of a fine yellow-green colour, which quickly deliquesce on exposure to the air. On mixing the solution of the normal sulphate in strong sulphuric acid with liquid sulphuric anhydride, the anhydrosulphate, (UO²)SO⁴.SO³, separates gradually in small yellow crystals. On heating the solution the salt separates immediately, but it is then generally mixed with the ordinary acid salt. It hisses when thrown into water (Schultz-Sellack, *Deut. Chem. Ges. Ber.* iv. 13).

III. Disulphuric, Pyrosulphuric, or Anhydrosulphuric Acid, SO²(OH)

Nordhausen Sulphuric acid (v. 574).—Several salts of this acid

have been examined by Schultz-Sellack (*Deut. Chem. Ges. Ber.* iv. 109). The acid itself is easily obtained of definite composition by mixing sulphuric acid with the liquid anhydride, using a slight excess of the latter, and spreading the resulting crystals under a bell-jar over not quite concentrated sulphuric acid, which then takes up the excess of the anhydride. If the mixture contains a large excess of the anhydride, it remains fluid for a long time, and on cooling yields a deposit partly consisting of the β-anhydride (p. 1135). The dry crystals melt at 35°, and exhibit no vapour-tension. The acid mixes with sulphurous anhydride, which can then be expelled only by prolonged boiling.

The pyrosulphates of potassium and sodium have been known for some time (v. 608, 612). The *neutral potassium salt*, K²S²O⁷, prepared by the action of sulphuric anhydride on the heated normal sulphate, melts, according to Jacquelin, at 210°, according to Schultz-Sellack at 300°, and cannot be recrystallised. By dissolving it in strong, fuming sulphuric acid, it is converted into *hydropotassic pyrosulphate*, KHS²O⁷, which crystallises in transparent prisms melting at 168°. The salts, Na²S²O⁷, Ag²S²O⁷, and BaS²O⁷, prepared like the potassium salt, form colourless crystals. The barium salt hisses when thrown into water; it does not melt when heated, but decomposes at an incipient red heat (Schultz-Sellack).

Potassium pyrosulphate in fine powder, heated with an alcoholic solution of potassium sulphhydrate, yields a considerable quantity of potassium thiosulphate:

The same salt, boiled with alcoholic sodium ethylate, yields potassium ethylsulphate:

(Drechsel, *J. pr. Chem.* [2], v. 367).

An *arsenious anhydrosulphate*, As²(SO³)²SO³, which may perhaps be represented by the constitutional formula:

separates from a solution of arsenious oxide in fuming sulphuric acid, in slender shining needles, which are decomposed by water. The corresponding *antimony-compound*, first obtained by Peligot (v. 584), may be prepared in a similar manner (Schultz-Sellack).

IV. **Iodosulphuric Acid**, $\text{H}^2\text{SO}^3\text{I}^2$ (p. 684).

V. **Thiosulphuric Acid**, $\text{H}^2\text{S}^2\text{O}^3 = \text{SO}^2 \begin{smallmatrix} \text{OH} \\ \text{SH} \end{smallmatrix}$. The salts of this acid have been examined by E. A. Letts (*Chem. Soc. J.* [2], viii. 424), who infers that they do not contain hydrogen as an essential constituent. He finds that the sodium salt, $\text{Na}^2\text{S}^2\text{O}^3 \cdot 6\text{H}^2\text{O}$, gives off the whole of its water at 100° , or in a vacuum over sulphuric acid; whereas, according to Papo (*1st Suppl.* 1073), a temperature of 215° is required to expel the last molecule of water. The *barium salt* crystallises with only one molecule of water, which is likewise expelled at 100° . The *lead salt*, PbS^2O^3 , is anhydrous, as previously shown by Papo. The *strontium salt* appears to contain 5 mols. water, four of which are given off at 100° ; whereas at 200° only $\frac{1}{2}$ mol. H^2O is expelled: hence Letts infers that the formula of the salt is $2\text{SrS}^2\text{O}^3 \cdot 10\text{H}^2\text{O}$, and that only 2 mols. of the water can be driven off without decomposition. The *magnesium salt*, $\text{MgS}^2\text{O}^3 \cdot 6\text{H}^2\text{O}$, gives off only 3 mols. water at 100° , the other three appearing to be retained till decomposition begins. The thiosulphates of *cobalt* and *nickel* contain 6 mols. water, and are easily decomposed.

Lead thiosulphate (1 mol.), treated with phosphorus pentachloride, yields, together with lead chloride, hydrogen chloride and sulphurous oxide, a distillate containing thionyl chloride, SOCl^2 , phosphorus oxychloride, and probably also phosphorus phosphochloride. The reaction begins spontaneously, but requires heat to complete it (J. Y. Buchanan, *Deut. Chem. Ges. Ber.* iii. 485).

VI. **Dithionic Acid**. On the crystalline form of lead thionate, see Brezina (*Jahrbuch. f. Mineralogie*, iv. 642).

VII. **Trithionic Acid**, $\text{H}^2\text{S}^3\text{O}^4$. Ammonium trithionate is formed, with evolution of hydrogen sulphide and ammonia, by the action of ammonium sulphate on manganous sulphide:

The hydrogen sulphide probably results from the decomposition of part of the trithionate: $(\text{NH}^4)^2\text{S}^3\text{O}^4 = 2\text{SO}^2 + (\text{NH}^4)^2\text{S}$. (F. Muck, *Deut. Chem. Ges. Ber.* iv. 146).

Potassium Selenio-trithionate, $\text{K}^2\text{SeS}^3\text{O}^4$, forms monoclinic crystals exhibiting the faces ∞P , $\infty\text{P}'$, $\infty\text{P}''$, $\infty\text{P}'''$, $\infty\text{P}''''$. Angle $\infty\text{P} : \infty\text{P}' = 112^\circ 42'$; $\infty\text{P}' : \text{P} = 142^\circ 6'$; $\text{P} : \text{P}' = 98^\circ 22'$ (B. Rathke, *J. pr. Chem.* [2] i. 33).

VIII. **Tetrathionic Acid**, $\text{H}^2\text{S}^4\text{O}^6$. When a mixed solution of a thiosulphate and iodate is treated with an acid, tetrathionate and iodate are produced, as shown by the equation:

SUPERPHOSPHATES, ANALYSIS OF. See PHOSPHATES (p. 970).

SUPERSATURATED SOLUTIONS. See SALINE SOLUTIONS (p. 1070).

SURFACE-TENSION OF LIQUIDS. See CAPILLARITY (p. 247).

SYMPHYTUM. The prickly comfrey (*S. aspernum*), a native of the Caucasus, is cultivated in some parts of Ireland as food for dairy-stock. The plant is perennial, is easily propagated by cuttings from the root, and yields a heavy crop. The ordinary produce is about 30 tons per acre, in several cuttings, but 82 tons has been reached. Analysis of plants grown in Oxfordshire gave the following results:—

	Natural state	Dried at 100°
Water	90.66	—
Oil and chlorophyll	0.20	2.20
Soluble nitrogenous compounds	1.10	11.81
Insoluble nitrogenous compounds	1.62	17.31
Gum, mucilage, and a little sugar	1.28	13.65
Woody fibre	3.30	35.43
Soluble mineral matters	1.25	13.32
Insoluble mineral matters	0.69	6.28
	100.00	100.00
Total nitrogen	0.434	4.66

Judging from its composition, the plant will have about the same feeding value as green mustard, turnip-tops, or Italian rye-grass grown on irrigated land (A. Voelcker, *Journ. Roy. Agr. Soc.* [2], vii. 387).

SYNANTHROSE, $C^{12}H^{22}O^{11}$. A sugar isomeric with cane-sugar, occurring, together with inulin, in the tuber-bearing *Compositæ* (see SUGARS (p. 1109)).

SYNGENITE. Potassio-calcic sulphate from the salt-beds of Kalusz in Galicia, Zepharovich (*Jahrb. f. Min.* 1872, 536) gave the name *syngenite* to a mineral of this composition, which he supposed to be rhombic, and J. Rumpf (*Min. Mitth.* 1872, 120) designated a monoclinic mineral of the same composition as *kalusite*. Subsequent investigation (*ibid.* 1873, 88, 638) having shown, however, that both minerals are monoclinic, and identical in form and composition with artificially prepared potassio-calcic sulphate, $K^2SO^4 \cdot CaSO^4 + H^2O$, the name *kalusite* has been dropped.

The first four of the following analyses (made on specimens originally called *kalusite*) are by Ullik (*Min. Mitth.* 1872, 120), the fifth by O. Völker (*Jahrb. f. Min.* 1873, 88). No. VI. gives the values calculated from the formula above given:

	I.	II.	III.	IV.	V.	VI. (calc.)
CaO . . .	17·24	17·09	16·67	16·62	16·97	17·06
MgO . . .	—	—	—	—	0·16	—
K ² O . . .	28·67	28·53	28·40	28·72	28·03	28·70
SO ² . . .	—	48·63	48·33	48·35	40·04	48·75
H ² O . . .	5·50	5·46	5·46	5·45	5·81	5·18
Sp. gr. . . .	2·53 to 2·55				22·5	

The axial elements are:

Clinodagonal	Orthodagonal	Principal axis	
1·3801	: 1	: 0·8667	Rumpf
1·3699	: 1	: 0·8738	Zepharovich.

Angle of inclined axes 76° 9' (Rumpf); 76° 0' (Zepharovich).

T

TACHYLITE. On the tachylite and dolerite of the Sababerg in Hesse, see **DOLERITE** (p. 439).

TADJERITE. The name given by Mounier to the rock composing the meteorite which fell at Tadjéra, near Setif, on June 9, 1867. On the black colouring matter of this rock, see Mounier (*Compt. rend.* lxii. 393; *Chem. Soc. J.* [2], ix. 329). On the conversion of serpentine into tadjerite: *Compt. rend.* lxxii. 541; *Chem. Soc. J.* [2], ix. 505.

TALCOSITE. A mineral from Victoria, where it occurs in thin laminar veins traversing selwynite. It feels like talc, has a silver-white colour, with a tinge of green or yellow and a nacreous lustre. The laminae are flexible and unelastic. Before the blow-pipe it becomes quite white, exfoliates, gives off water, and melts to a blistered enamel. Hardness = 1; at right angles to the lamination, = 1·5 to 2·0. Sp. gr. = 2·46 to 2·5 (Ulrich, *Silk. Am. J.* [2], i. 272). C. Newbery found, as the mean of two analyses, 40·04 p.c. SiO^2 , 45·98 Al^2O^3 , and 4·80 H^2O , with traces of chromic, ferrous, and manganous oxides.

TAMMITE. This name is proposed by Crookes for a mineral of unknown origin, analysed by H. Tamm (*Chem. News*, xxvi. 13). It has a specific gravity of 12·5 and contains 88·05 p.c. tungsten, 5·60 iron, 0·15 manganese, and 6·20 undetermined substance, said to contain neither oxygen nor sulphur.

TAMPICIN, $C^8H^{14}O^{14}$ (Spirgatis, *N. Rep. Pharm.* xix. 452). A neutral substance resembling convolvulin, existing in *Tampero Jalap*. The tubers having been exhausted with water, the resin is extracted with alcohol, purified by boiling with water, and decolorised in alcoholic solution with animal charcoal. It dissolves in alcohol and in ether, and when treated with strong bases takes up $3H^2O$, and is con-

verted into tannic acid, $C^{12}H^{10}O^8$. This acid is amorphous, hygroscopic, easily soluble in water and in alcohol; neutral lead acetate and mercuric chloride, added to its solution, produce white clouds; basic lead acetate, a bulky precipitate.

Tannicin is resolved, by digestion with dilute acids, into sugar and tannic acid, $C^{12}H^{10}O^8$, which crystallises in slender needles, melts when heated to a faintly yellowish liquid, forms soluble salts with alkalis, insoluble salts with the earths and heavy metallic oxides.

The medicinal action of tannicin resembles that of convolvulin.

TANNIC ACID and **TANNIN**. The nature and constitution of tannic acid from nut-galls (gallotannic acid) have been investigated by H. Schiff (*Deut. Chem. Ges. Ber.* iv. 231, 967; further, *Bull. Soc. Chim.* [2], xviii. 23). There is no doubt that crude tannic acid contains glucose, and that this substance is not merely mechanically retained in it; the percentage of sugar, however, has been very variously estimated by different observers, and it has been found possible, by appropriate treatment, to reduce the amount to a small percentage, the tannic acid thus purified exhibiting precisely the same properties as before. It has, therefore, long been a matter of dispute whether tannic acid was to be considered as a glucoside or not. The following experiments throw important light on the subject.

Well-purified crystallised tannic acid, dried at 110° , was mixed with phosphorus oxychloride to the consistence of an emulsion, and the mixture heated, first at 100° , afterwards at 120° , whereupon much hydrochloric acid was evolved, and the tannic acid was finally converted into a yellow powder which was washed several times by decantation with dry ether, and the residue, freed from ether by gentle warming, was dissolved in a small quantity of water. At the end of twelve hours a crystallisation of unchanged tannic acid (about 10 per cent.) was obtained. On saturating the yellow-red mother-liquor with salt, the whole solidified; and on the addition of more salt, the precipitate caked together to a resinous mass, from which the greater part of the salt-solution could be poured off. After twice washing with salt-solution, the resinous cake was dried in a vacuum, dissolved in absolute alcohol, and a considerable volume of ether was added to the solution, which was then filtered; after distilling off the ether, the mass was dried in a vacuum. The varnish-like slightly coloured residue thus obtained exhibits the reactions, solubility, physical properties, taste, &c., characteristic of tannic acid. It is the first tannic acid which has been prepared perfectly free from sugar. By heating with hydrochloric acid it was entirely converted into crystalline gallic acid, and this again into tannic acid. Analyses of various portions gave 51.7 to 52.3 per cent. C, and 3.4 to 4.1 per cent. H, agreeing with the formula $C^{12}H^{10}O^8$, which is that of an anhydride of digallic acid: $C^{12}H^{12}O^{10} - H_2O = C^{12}H^{10}O^8$. The tannic acid thus prepared is converted, by the action of acetic anhydride, into an acetyl-derivative which Schiff formerly supposed to be tetracetyl-tannic acid, whence he was led to regard tannic acid as an alcoholic anhydride of digallic acid containing four OH groups, and represented by the formula:

Subsequent experiments, however, have shown that this supposed tetracetyl-derivative is really a pentacetyl-tannic acid, whence it follows that the molecule of tannic acid must contain five hydroxyls, and must be represented by the formula:

which is that of an etherated anhydride of digallic acid.

Ellagic Acid, $C^{12}H^6O^8$.—This acid is formed, according to Griessmayer (*loc. cit.*), by the action of iodine on tannic acid:

It is also formed in small quantity by the action of phosphorus oxychloride on tannic acid, or of the pentachloride on gallic acid, and when acetyl-tannic acid is boiled with magnesia and water, and the product is exposed to the air (Schiff); moreover, as observed by Löwe, when tannic acid is heated with dry arsenic acid:

Ellagic acid dried at 110° has the composition $C^{12}H^6O^8$, and its relation to tannic acid may be represented as follows:—

Air-dried ellagic acid, $\text{C}^{14}\text{H}^8\text{O}^8 + \text{H}_2\text{O}$, loses its water at 100° , but re-absorbs it from moist air. When it is heated to 200° – 210° , the compound $\text{C}^{14}\text{H}^8\text{O}^8$ is obtained, and this compound does not recover its water from moist air, but ebullition with water slowly reconverts it into ellagic acid. Consequently it is an anhydride of ellagic acid, and may be represented by one of the following formulae:—

The action of acetic anhydride on ellagic acid (dried at 100°) gives rise to the formation of *tetracetyl-ellagic anhydride*. This compound forms a yellow crystalline powder, slightly soluble in water, alcohol or ether, and dissolving in sulphuric acid with the production of a yellow colour. Its constitution may, perhaps, be represented by the formula:

Natural Tannin. The above investigations prove that natural tannin is not a glucoside of gallic acid, and Schiff finds that pure pentacetyl-tannic acid may be obtained by the action of acetic anhydride on natural tannin, any glucose present being acetylated and subsequently removed by the action of water. That the glucose present in imperfectly purified natural tannin does not exist in the free state, is proved by the fact that ether-alcohol and anhydrous alcohol dissolve such tannin freely. Unaltered natural tannin is probably a glucoside of digallic acid:

This formula corresponds with 23 p.c. of glucose, and the amount of this substance obtained from natural tannin varies from 0 to 22 p.c., according to the extent to which the tannin has been purified. Schiff proposes to confine the term tannin to the glucoside, and to use the term *digallic acid* instead of tannic acid for indicating the product which yields no sugar (Schiff).

J. Löwe (*Zeitschr. anal. Chem.* 1872, 365; *Chem. Soc. J.* [2], xi. 748) also finds that pure gallotannic acid is not a glucoside, and that when dried at 140° – 145° it has the composition $\text{C}^{14}\text{H}^{10}\text{O}^8$.

Gallotannic acid is not found in oak-bark, catechu, or other materials used in tanning. Even the tannin of the sumach exhibits different properties, and its analysis leads to the formula $\text{C}^{16}\text{H}^{14}\text{O}^{10}$ (Löwe).

On the preparation of tannic acid from nut-galls, see Rothe (*Arch. Pharm.* [2], cxlii. 232; *Jahresb.* 1870, 567).

Reaction of Gallotannic Acid with Iodine and Alkali.—When a drop of tannic acid solution is mixed with a cubic centimeter of $\frac{1}{10}$ normal iodine-solution, the liquid on agitation immediately becomes colourless (with formation of gallic and ellagic acids); and if to this mixture there be added 1 c.c. of a spring water, which when boiled down to a small bulk exhibits only a faint alkaline reaction, a brilliant red coloration is produced, which lasts for a long time (Griessmayer, *Zeitschr. anal. Chem.* 1872, 43).

On the reaction of Tannic acid with Iodine and Starch, see Brauch (p. 1099).

Estimation of Tannin.—An elaborate memoir on the estimation of oak-bark tannin (quercitannin) has been published by C. Neubauer (*Zeitschr. anal. Chem.* 1871, 10; 1-40; *Chem. Soc. J.* [2], ix. 594-600; *Jahresb.* 1871, 964). Of the various methods in use, he gives the preference to that of Löwenthal, which is based on the use of a solution of potassium sulphindylate (indigo-carmine) standardised with permanganate. Wagner's method, founded on the precipitation of the tannin by cinchonine, Neubauer regards as unsound, inasmuch as even when the cinchonine solution is added in large excess, the filtrate still contains tannin.

A discussion of the different methods in use for the estimation of tannin in catechu, ratanhia, kino, and other tanning materials is given by Günthor (*Russ. Zeitschr. Pharm.* ix. 161, 194, 225; *Vierteijahrschr. pr. Pharm.* xx. 214-238; *Chem. Centr.* 1871, 395).

On the use of tannin for the preservation of Wine, see *Dingl. pol. J.* cci. 376.

Contributions to the technology of the tannins: R. Wagner (*ibid.* ccv. 137-144).

Endeavours to establish the art of tanning on a scientific foundation: A. Reimer (*ibid.* ccv. 143, 248, 358, 457; *Jahresb. f. Chem.* 1872, 1016).

Alder Tannin. The coloured tannin of alder-wood has been examined by F. Dreykorn a. E. Reichardt (*Dingl. pol. J.* xciv. 157). The fresh sawdust of the wood of *Alnus glutinosa* was exhausted in an extraction-cylinder with boiling water; the dark red-brown filtrate precipitated with lead acetate; and the well-washed precipitate decomposed by hydrogen sulphide, the bulk of the colouring matter being thus thrown down together with the lead sulphide. The precipitate was washed with cold water, and the colouring matter extracted with boiling alcohol of 90 p.c. On distilling off the alcohol and drying the residue in the water-bath, there remained a brown resinous mass reducible by trituration to a red-brown powder.

The analysis of this body dried at 130° leads to the formula $C^{27}H^{20}O^{11}$. It is almost insoluble in ether, benzene, and carbon sulphide, dissolves with difficulty in absolute alcohol, more easily in boiling water, in all proportions of dilute alcohol. It precipitates gelatin, and produces a dirty green coloration with ferric chloride. By precipitating its hot aqueous solution with lead acetate, a lead compound is obtained having the composition, $PbO.C^{27}H^{20}O^{10}$; the copper-compound contains $3CuO.H^2O.4C^{27}H^{20}O^{10}$.

Alder Red.—Alder tannin treated with dilute sulphuric acid (1 : 10) for 24 hours at the heat of the water-bath is resolved into sugar (18 to 19 p.c.; a fermentation experiment gave only 16 p.c.), and a red-brown resinous deposit of alder red, which when dried at 130° has the composition $C^{16}H^{12}O^{13}$, and when dried over sulphuric acid, $C^{16}H^{12}(O^{13})^{13}H^2O$. This substance is insoluble in water and in ether, slightly soluble in alcohol; caustic soda and ammonia dissolve it, forming a liquid of light red-brown colour, from which it is precipitated in flocks on acidulation; on exposure to the air, the alkaline solution becomes darker and deposits black-brown flocks. On adding lead acetate to a strongly ammoniacal solution of alder red, a brown precipitate is formed which, after drying at 130°, has the composition $2PbO.C^{16}H^{12}O^{11}$. The resolution of alder tannin into alder red and sugar may be represented by the equation:

which requires 22.1 p.c. of grape-sugar.

Alder tannin yields, by fusion with potash, protocatechuic acid, phloroglucin and acetic acid; and by dry distillation, pyrocatechin. As it is also split up by ferments, it is conceivable that the red colour which fresh alder-wood acquires by exposure to the air may be produced by alder red, the decomposition-product of alder tannin; at all events, the intensity of the colour agrees well with this supposition.

TANTALATES and NIOBATES. The following formulae for these minerals, deduced from numerous analyses, are given by Rammeisberg (*Berl. Acad. Ber.* 1871, 157, 406, 584; *Deut. Chem. Ges. Ber.* iv. 874; *Chem. Soc. J.* [2], ix. 196-204).

1. *Tantalite* and *Niobite* (columbite) $\{nFeTa^3O^8\}$, with isomorphous admixtures of the salts, $FeSnO^3$, $FeTiO^3$, $FeWO^3$.

2. *Tepiolite* is quadrate tantalite.

3. *Polycrase* and *Euxenite* differ from one another only as isomorphous mixtures. Crystallised polycrase contains 4 p.c. tantalic acid.

R = Y, Eb, Ce, U, Fe.

Water is present occasionally, but not as an essential constituent.

4. *Fergusonite*, *Yttrotantalite*, *Tyrite*, *Bragite*.—A combination of the same metals according to the formula $R^2Nb^2O^6$, or $3R^2O.Nb^2O^3$. Crystallised fergusonite from Greenland contains 1Ta : 12Nb. In these minerals also the water (sometimes amounting to 6 p.c.) is only a secondary constituent.

5. *Pyrochlore*.—Specimens from different localities show great diversity of composition, the only constant constituents being R=Ca and Ce, as also NaF. The analyses lead to the following formulæ: I. Miask; II. Brevig, containing uranium; III. Frederiksvärn, free from Th. and U., rich in Fe; IV. Kaiserstuhl.

For the analyses, see the paper above cited in the *Journal of the Chemical Society*; also the article TANTALUM in this dictionary, vol. v. pp. 667-669.

There are two tantalum and niobium minerals not included in these analyses, viz.: *samarskite* and *æschynite*. *Samarskite* is a niobate of uranium, yttrium, and iron (iv. 55); *æschynite*, a mixture of niobates, titanates, and thorates of Co, La, Ca, and Fe,

represented by the formula $\left\{ \begin{array}{l} RNb^2O^6 \\ 2R(Ti,Th)O^3 \\ (Ti,Th)O^3 \end{array} \right\}$ (1st Suppl. 58).

A comparison of the composition of the natural tantalates and niobates, with their crystalline forms, exhibits several interesting series of isomorphous and heteromorphous bodies.

A. Isomorphous Groups of the Rhombic System.

	Ratio of the axes	
	a.	c.
Tantalite, Niobite	0.82	0.82
Wolfram	0.83	0.87
Tantalie acid	0.83	0.82
Tungstic acid	0.83	0.87
Titanic acid (Brookite)	0.84	0.94
Polycrase (Euxenite)	0.94	0.91
Æschynite	0.49	0.67
Wochlerite	0.99	0.75
Bronchite (MgSiO ³)	1.03	1.18

B. Isomorphous Groups of the Quadratic System.

	Ratio of the axes	
	a.	c.
Tapiolite	0.62	0.64
Titanic acid (Rutile)	0.63	0.64
Zircon ((Zr.Si)O ²)	0.63	0.64
Tin ore (SnO ²)	0.63	0.67
Zirconic acid	1.00	1.00
Thoric acid	0.16	0.16
Xenotime (Y ³ P ⁵ O ¹⁴)	0.62	0.62
Fergusonite	1.50	1.50
Scheelite (CaWO ⁴)	1.53	1.53
Scheelbleierz (PbWO ⁴)	1.57	1.57
Gelbbleierz	1.58	1.58

Hence it may be inferred:

1. The molecules RTa^2O^6 , RWO^4 , $RTiO^3$ are isomorphous with the anhydrides Ta^2O^3 , WO^3 , TiO^3 .

2. All these molecules are dimorphous. The regular form of pyrochlore is also connected with the forms of its component minerals. KF and NaF , like $CaTiO^3$ (perovskite) are regular, and the same crystalline form is to be found in BaN^2O^6 , SrN^2O^6 , PbN^2O^6 .

The tantalates and niobates hitherto found in minerals are RNb^2O^6 , $R^2Nb^2O^7$, $R^2Nb^2O^8$, corresponding with the phosphates and arsenates.

TANTALUM. On the separation of this metal (and of niobium) from tin, titanium, and tungsten, see Rammelsberg (*Chem. Soc. J.* [2], x. 193, 194).

TARTARIC ACID, C⁴H⁴O⁶. *Formation from Oxalic Acid.*—This acid is formed, together with glycollic and glyoxylic acids, by the action of sodium-amalgam on ethylic oxalate in alcoholic solution:

(Debus, *Chem. Soc. J.* [2], x. 376); see also p. 569 of this volume.

On the Recovery of Tartaric and Oxalic acids from the residues of the Discharge process, see p. 881.

On the Heat of Neutralisation of Tartaric acid, see H₂AT (p. 621).

Reaction with Potassium Permanganate.—This reaction takes place differently according as a mineral acid is added or not. To produce a permanent red coloration when no mineral acid is added, requires only half the quantity of permanganate solution that is necessary when an acid is added. In the former case a manganese tartrate, $C^4H^4MnO^4 + 2H^2O$, is formed, which is rose-coloured while moist, but becomes paler when dry, and is nearly colourless at 100° and higher temperatures. 1000 pts. of water dissolve 2.17 pts. of this salt. The boiling solution mixed with alcohol deposits small hard crystals. No acid salt is formed in the reaction (W. A. Fleischer, *Deut. Chem. Ges. Ber.* v. 350).

On the Detection of Tartaric acid crystals in Citric acid, see p. 346.

Conversion of Dextrotartaric acid into Racemic acid and Inactive Tartaric acid.—This transformation may be effected by heating the acid in sealed tubes. 30 grams of dextrotartaric acid are sealed up with 3 to 4 grams of water in strong tubes, and heated in an oil-bath to 175° for thirty hours. On opening the tubes a large quantity of gas escapes. The product is taken up by boiling water, and the solution is filtered and evaporated. If the concentration has not been carried too far, the crystals which separate consist entirely of racemic acid. The mother-liquor, which contains unaltered dextrotartaric acid, the inactive acid, and products of decomposition, yields, when again heated in sealed tubes, a further quantity of racemic acid. The temperature must be maintained exactly at 175° , since at higher temperatures the tartaric acid is decomposed, and at lower temperatures the transformation is very slow. The racemic acid thus obtained exhibits all the properties of that which is prepared from tartar. When the tartaric acid is heated without addition of water, the quantity of racemic acid obtained is smaller. For operations on a large scale, the materials may be heated in a wrought-iron autoclave. 650 grams of dextrotartaric acid and 100 grams of water thus heated to 180° yielded more than 100 grams of racemic acid. If the heat be continued long enough, the dextrotartaric acid disappears completely, while the quantities of racemic and inactive tartaric acid in the product bear to one another a certain fixed relation. To reconvert the inactive tartaric acid into racemic acid, it is necessary first to remove the racemic acid already formed. Consequently, pure inactive tartaric acid cannot be completely transformed into racemic acid by one treatment in the manner above described. Both the degree of heat and the quantity of water added have an influence on the state of equilibrium of the two acids in the mixture. Inactive tartaric acid may be obtained in considerable quantity by heating dextrotartaric acid with the above-mentioned quantity of water in the autoclave for two days to only 165° . After the small quantity of racemic acid formed at the same time has been removed by a first crystallisation, the mother-liquor is divided into two equal parts, one of which is neutralised with potassium carbonate, and then added to the other half. By this means the remainder of the racemic acid and the unaltered dextrotartaric acid may be removed in the form of thin, sparingly soluble, acid potassium salts. The mother-liquor of these salts yields the acid potassium salt of inactive tartaric acid, and on converting this into the calcium salt by precipitation, decomposing the latter with sulphuric acid, and filtering, the filtrate deposits free inactive tartaric acid in crystals (Jungfleisch, *Bull. Soc. Chim.* [2], xviii. 201).

TARTRONIC ACID. On the formation of this acid by the action of cupric oxide in alkaline solution on dextroglucose, see SUGARS (p. 1104).

TARTROPHETHALIC ACID, $C^8H^{10}(OH)O^4$. An acid formed by heating bromomalopthalic acid, $C^8H^8Br(OH)O^4$, with baryta-water. See TETRAHYDRO-PHTHALIC ACID (p. 1149).

TAURINE. *Behaviour in the Animal Organism.*—Schultzen considers the origin of urea and of sulphates in the urine to be due to the decomposition of bile-acids, first into cholic acid (excreted in the fæces), glycocine, and taurine, and finally into urea and sulphates, the sulphur in the taurine being thus viewed as oxidised in the body.

When men and dogs were fed on food impregnated with taurine, no increase of sulphates in the urine was noticeable, but almost all the taurine was excreted unchanged in the urine, no production of thiosulphates being discernible, even when 15 grams of taurine were given in three days; when, however, vegetable feeders, such as rabbits, were experimented on, only about $\frac{1}{4}$ or less of the taurine was unattacked, about $\frac{3}{4}$ being excreted as an alkaline thiosulphate, and more than $\frac{1}{4}$ as a sulphate, this latter being probably due to a secondary action, whereby the thiosulphate became oxidised.

It hence appears that in vegetable feeders the sulphates in the urine are at any rate partially derived from taurine proceeding from the decomposition of bile; the whole of the urea, however, cannot be due to these changes, inasmuch as the relative quantities of nitrogen and sulphur daily excreted are very different from those which should

be present on Schultzen's supposition, the nitrogen being greatly in excess. Moreover, it is found that the normal urine of dogs fed on bread and milk contains only $\frac{2}{3}$ of its sulphur as sulphates, the rest being in the form of sulphurized organic substances, so that the whole of the sulphur of the taurine formed is not oxidised to sulphate (E. Salkowski, *Deut. Chem. Ges. Ber.* v. 637).

TAUROCHOLIC ACID. On the estimation of this acid in bile, see Külz (*Zeitschr. anal. Chem.* 1872, 353; *Jahresb. f. Chem.* 1872, 939; *Chem. Soc. J.* [2], xi. 536).

TEA. The difference in the quality of different samples of tea arises, not from their being the leaves of different species of tea-plant, but partly from the nature of the soil and manner of cultivation, and chiefly from the age of the leaves, the youngest leaves, other things being the same, yielding the best tea. The constituents of the ash of tea-leaves vary with their growth, the quantity of limo and silica increasing both absolutely and relatively with their age, whilst the potash and phosphoric acid decrease; and, as the best tea is prepared from the youngest leaves, an analysis of the ash would appear to be the simplest method of determining the quality of a tea. To test the truth of this inference, Ph. Zöller (*Ann. Ch. Pharm.* clviii. 180) examined a specimen of very fine and carefully made Himalaya tea, of a fine black colour, and consisting of very young lancet-shaped leaves. It contained 4.95 p.c. water, and 5.63 of ash, 100 pts. of which contained 39.22 of potash, 14.55 of phosphoric acid and only 4.24 of lime. As the tea consisted of very young leaves, and its ash was so rich in potash and phosphoric acid, it might be expected to yield a large amount of nitrogenous matter and of theine, and also of total extract. The nitrogen amounted to 5.38 p.c., and the extract, obtained by infusing 100 grams in three litres of boiling water twice successively, was 36.26 grams. To determine the theine, the tea was heated to 100° with slightly diluted sulphuric acid, treated with lead hydrate to remove the acid, and exhausted with 86 p.c. alcohol. The pale-coloured solution, on standing, deposited crystals which appeared to be theobromine, and the mother-liquor from these was found to contain 4.94 p.c. theine. No theobromine could be detected in two samples of the best tea of commerce used for comparison. Peligot's analysis (*ibid.* xlvii. 360) are the only published ones giving such high numbers for nitrogen and theine.

The extract gave 3.56 p.c. nitrogen, and 4.04 of ash, the latter containing 55.15 p.c. of its weight of potash, 7.89 phosphoric acid, and only 0.95 lime. The exhausted leaves gave 2.26 p.c. nitrogen and 1.80 of ash, containing only 7.34 of potash, but 25.41 phosphoric acid, and 10.79 of lime. It remains undetermined whether Himalaya tea is distinguished from Chinese tea by containing theobromine, but it would appear that the specimen examined was equal to the best Chinese tea.

The numbers above given show how easy it is, by an analysis of the ash, to detect a tea consisting of exhausted leaves which have been re-dried, since they become comparatively poor in potash salts and rich in lime. Zöller believes that the value of tea as a beverage is due, not only to the theine it contains, but also to the other nitrogenous substances present, and to the large amount of potassium salts.

Aubert (*Dingl. pol. J.* cxi. 500) finds that a cup of good Pekoe tea, prepared from 5 to 6 grams of the leaves, contains from 0.1 to 0.12 gram of theine, which is about the same amount as that contained in the infusion of half an ounce of good coffee.

TELLURIUM. *Preparation.*—According to F. Stolba (*Dingl. pol. J.* cxviii. 262), tellurium is completely precipitated from a solution of tellurous acid in excess of caustic potash or soda by boiling with grape-sugar; he recommends this method for the working of tellurium ores. Selenious acid is not reduced under the same circumstances.

Spectra.—On the spectrum of tellurium vapour, see Salet (*Compt. rend.* lxxiii. 559, 742); Ditte (*ibid.* 822); also *Chem. Soc. J.* [2], ix. 1145, 1146.

Tellurous chloride may be obtained by the action of dry chlorine on tellurium in a narrow tube, as a black mass which liquefies at a red heat, and volatilises in yellow vapours. A stratum of the vapour only a centimeter thick gives a peculiar spectrum, particularly well developed in the orange and green. *Tellurous bromide* gives a violet vapour, having its principal spectral lines in the red and yellow (Garnier, *Compt. rend.* lxxiv. 465).

On the Heat of Combustion of Tellurium, see Hnat (p. 613).

On the Reaction of Tellurium with Sulphuric anhydride, see SULPHUR (p. 1136).

Hydrogen Telluride, TeH_2 , is decomposed by heat in the same manner as hydrogen selenide (p. 1079). By enclosing tellurium in a tube filled with hydrogen, and heating only the part of the tube where the tellurium is placed, it is deposited on the cold part of the tube in prisms 20 mm. long (Ditte).

TEREPHTHALIC ACID. See PHTHALIC ACID (p. 979).

TERPENES, $C^{10}H^{16}$. On the physical character of terpenes, see OILS VOLATILE (p. 872); on their refractive indices, *LIGHT* (pp. 740, 741).

On the formation of Cymene from terpenes, see CYMENE (p. 419).

TERTIARY ALCOHOLS. *Oxidation.*—The oxidation of tertiary alcohols takes place according to a law similar to that which rules the oxidation of ketones (p. 711), the most simple alcohol-radicle remaining combined with the carbon-atom by which the whole group is kept together, whilst the two other radicles are oxidised separately. The only exception to this rule appeared to be made by trimethyl-carbinol, which, as Butlerow formerly found, yielded acetone, acetic acid, and propionic acid. But on studying the oxidation-products of this alcohol more closely, he now finds (*Zeitschr. f. Chem.* [2], vii. 484) that they consist chiefly of acetone (being an intermediate product) and acetic acid, besides a smaller quantity of isobutyric acid. The formation of this latter compound is not in contradiction to the above law; it is formed by a molecular change, corresponding with that by which Linnemann has found that derivatives of trimethyl-carbinol are obtained from isobutyl alcohol (p. 219).

TETRAHYDROPHTHALIC ACID, $C^8H^{10}O^4$ (Baeyer, *Deut. Chem. Ges. Ber.* iii. 61; iv. 273). This acid is formed, with copious evolution of carbon dioxide, when hypopyromellitic acid (1st *Suppl.* 812) is heated. Tetrahydrophthalic anhydride, $C^8H^8O^3$, then distils over in the form of an oil, which solidifies in large laminae on cooling. This anhydride melts at 68° and distils in comparatively small quantities without alteration; it is insoluble in water, easily soluble in ether, and crystallises therefrom by spontaneous evaporation in hard shining laminae. It dissolves at a moderate heat in strong sulphuric acid, and is precipitated by water in large laminae. At a stronger heat gas is evolved, and the anhydride gradually undergoes complete decomposition without formation of phthalic or benzoic acid. The anhydride, when boiled with water, is converted into the easily soluble acid, $C^8H^{10}O^4$, which crystallises in laminae, melts at 96° , and is at the same time reconverted into the anhydride.

Tetrahydrophthalic acid is bibasic. When heated with distilled hydriodic acid it takes up 2 at. of hydrogen and is converted into hexhydrophthalic acid, $C^8H^{12}O^4$. The same compound is formed by the action of sodium-amalgam on tetrahydrophthalic acid, 2 at. of hydrogen appearing to be the largest amount that this acid is capable of taking up. This behaviour indicates that tetrahydrophthalic acid belongs to the series of benzocarbonic acids (1st *Suppl.* 809); Baeyer represents it by the constitutional formula:

This view of its structure is perfectly in accordance with its behaviour to bromine. When 2 at. bromine are added to its aqueous solution, a liquid is obtained which, when evaporated over sulphuric acid, yields hard crusts of bromomalophthalic acid, $C^8H^{10}Br(OH)O^4$. This acid dissolves freely in water, and is very easily decomposed. When heated with baryta-water it forms barium bromide and the barium salt of tartrophthalic acid, $C^8H^{10}(OH)^2O^4$. This last acid is very soluble in water, and crystallises therefrom in very large, finely developed prisms. When somewhat strongly heated it distils, leaving only a small residue. The syrupy distillate has a peculiar odour like that of the less hydrogenised aldehydes, and contains unaltered tartrophthalic acid, together with other substances. The acid is bibasic. Its barium salt separates in the cold in thin laminae, from warm solutions in granular prisms. The lead salt, $C^8H^{10}O^4.Pb$, crystallises in concentrically-united slender needles, very sparingly soluble in water.

Hexhydrophthalic acid, $C^8H^{12}O^4$, is formed, as already stated, by the action of hydriodic acid or sodium-amalgam on tetrahydrophthalic acid; also, according to Mizorski (*Deut. Chem. Ges. Ber.* iv. 558), by heating hydrophthalic acid, $C^8H^8O^4$ (1st *Suppl.* 842), with hydriodic acid to 240° – 250° . It melts at 207° (Mizorski), at 203° – 205° and solidifies in needles (Baeyer). It is a bibasic acid, and forms a crystalline lead salt, $C^8H^{10}O^4.Pb + H^2O$ (Baeyer).

The formation of this acid from hydrophthalic acid is accompanied by that of another acid much more soluble in water, and melting at 163° – 167° , also by that of a very small quantity of a hydrocarbon (Mizorski).

TETRAMINES, CHROMIC. See CHROMIUM (p. 336).

TETRAPHENOL. This name is given by Limpricht to a compound, $C^6H^4O^2$, produced by distilling barium pyromucate with soda-lime (p. 1032).

TETRAPHENYLETHYLENE, $C^6(C^6H^5)^4$ (A. Behr, *Deut. Chem. Ges. Ber.* iii. 751; v. 277). This hydrocarbon is formed by the action of finely divided silver on the chloride, $C^6(C^6H^5)^2Cl^2$, obtained by treating benzophenone with phosphorus pentachloride (p. 176), and separates from solution in hot benzene in spicular crystals melting at 221° . On mixing its solution in glacial acetic acid with half its weight of chromic acid, likewise dissolved in glacial acetic acid, and boiling till the liquid turns green, the solution, on cooling, becomes filled with green needles of tetraphenylethylene oxide, $C^6(C^6H^5)^4O$, which, after several recrystallisations from glacial acetic acid, is obtained pure and melting at 193° – 194° . The oxide dissolves in benzene and in ether, volatilises without residue when strongly heated, and is converted by chromic acid in excess—as also the hydrocarbon itself—into benzophenone:

Strong sulphuric acid converts tetraphenylethylene or its oxide into tetraphenylethylene-tetra-sulphonic acid, which, however, has not been obtained pure; its salts are easily soluble and uncrystallisable. On fusing the barium salt with three times its weight of potassium hydrate, tetraoxyphenyl-ethylene, $C^6(C^6H^4OII)^4$, is produced. This compound crystallises from acetic acid and melts above 300° . Ferric chloride dissolved in glacial acetic acid oxidises it to a crystalline body, $C^6II^4O^4 \cdot \frac{1}{2}H^2O$, which gives off its water at 180° . The crystals are green, with metallic lustre, and yield a red powder. They are insoluble in water, ether, chloroform, and benzene, slightly soluble in alcohol. Alkalis dissolve them with deep-blue green colour, and the concentrated solution yields, with acids, light or dark red precipitates. With alum the alkaline solution forms a dingy-red alumina-compound. The alkaline solution is easily reduced by zinc-dust. Behr regards this colouring matter as analogous in constitution to quinhydrone:

Quinhydrone

Colouring matter from
Tetraoxyphenylethylene

TETRAPHENYL-METHANE, $C(C^6H^5)^4$, appears to be formed, together with benzophenone, by the dry distillation of barium benzoate, passing over chiefly in the higher boiling portions of the distillate (Behr, *Deut. Chem. Ges. Ber.* vi. 971).

TETRASALICYLIDE. See SALICYLIC ANHYDRIDES (p. 1067).

TETROLIC ACID, $C^6H^4O^2$. A solid acid, said by Gauthier to be formed by the action of melting potash on the less volatile modification of monochlorocrotonic acid (p. 390).

TETROBYTERIN. A colouring matter obtained from the red spots over the eyes of the black-cock and pheasant; also from the reddish parts of the trout, the crab, and the fruit of *Phialopsis rubra*. It is soluble in chloroform, unchanged by caustic potash; concentrated sulphuric acid turns it indigo-blue, then black. It is also soluble in carbon sulphide and ether. It differs from the colouring matter of blood (Wurm, *Pogg. Ann.* cxlv. 170).

THALLIUM, Tl. *Atomic weight.*—Crookes has redetermined the atomic weight of this metal by ascertaining the quantity of thallous nitrate, $TlNO^3$, obtained by treating a known weight of thallium with nitric acid in a bulb-apparatus exhausted of air, with elaborate precautions to prevent access of atmospheric oxygen, and to eliminate any sources of error arising from inaccuracy in the weights employed, &c. The mean of ten closely agreeing determinations gave:

$$Tl = 203.642,$$

the minimum and maximum values being 203.628 and 203.666 (*Phil. Trans.* 1872; *Proc. Roy. Soc.* xx. 476).

Occurrences.—Thallium has been found in sphalerite from Geroldseck in the Breisgau (v. Kobell, *J. pr. Chem.* [2], iii. 176).

Preparation.—For the reduction of thallium from the chloride, Wöhler (*Ann. Ch. Pharm.* cxliv. 74) recommends the fusion of an intimate mixture of 20 pts. thallium chloride, 8 pts. sodium carbonate, and 1 pt. lampblack, at a low red heat. The slight

loss that may arise from volatilisation of the chloride at the commencement of the operation, may perhaps be avoided by making the mass into a paste with water, and drying it before fusion.

Preservation.—Böttger (*Dingl. pol. J.* cxvii. 379) recommends the keeping of thallium in distilled water freed from air. Thallium thus preserved was found to be quite unaltered after three years.

Chlorides, Bromides, and Iodides (Rammelsberg, *Pogg. Ann.* cxlvi. 592). *Thallium sesquichloride*, Tl_2Cl_3 (or rather Tl_2Cl^6), formed by melting thallious chloride in a stream of chlorine, is obtained in yellow scales. The same compound is formed when the brown oxide is dissolved in hydrochloric acid, and the solution evaporated.

Potassio-thallic Chloride, $3KCl.TlCl^3 + 2H^2O$, obtained by adding potassium chloride to a solution of the brown oxide in hydrochloric acid, forms large transparent crystals belonging to the quadratic or dimetric system. Almost similar crystals are obtained of the corresponding ammonium salt by using ammonium chloride in the place of potassium chloride. These salts are not decomposed by boiling with water, but are decomposed by alkalis, with separation of brown oxide of thallium.

Potassio-thallic Bromide, $3KBr.2TlBr^3 + 3H^2O$, is obtained by first precipitating the bromide of thallium, which is then dissolved by digestion with bromine-water, and, on the addition of potassium bromide, the double salt is formed. It is obtained in slightly yellow crystals, which appear to belong to the regular system.

Potassio-thallic Iodide, $3KI.2TlI^3 + 3H^2O$, is obtained by digesting thallious iodide with solution of potassium iodide and free iodine. By evaporation over sulphuric acid, the solution gives dark crystals which, when powdered, are of an intense dark red colour. The crystals belong to the regular system; on slight heating they lose iodine, and are converted into a mixture of potassium iodide and thallious iodide.

Thaloso-thallic Iodide, TlI^4 or $5TlI.2TlI^3$, is prepared by heating thallious iodide with strong hydriodic acid and iodine, and evaporating to dryness (at 70°); by digesting thallious iodide with excess of iodine in ethereal solution; by dissolving thallious iodide in a solution of iodine in absolute alcohol, evaporating over sulphuric acid and washing the residue with absolute alcohol, or by precipitating a soluble thallic salt with potassio-thallious iodide. The last method, however, does not easily yield it pure (Jørgensen, *J. pr. Chem.* [2], vi. 82).

When a solution of thallious iodide in hydriodic acid mixed with iodine is slightly supersaturated with ammonia, and this solution is added by portions to a moderately dilute and gently warmed solution of *cuprammonium sulphate*, the double salt, $4NH^3.CuI^2.2TlI^3$, is precipitated in shining needles, which may be quickly washed with cold water and dried in the pressed state over calcium chloride. It is decomposed by prolonged washing, also by ammonia, in which it partly dissolves. Alcohol dissolves it with greenish-yellow colour. Heated to 120° it leaves a mixture of thallious and cuprous iodides, and when it is heated with zinc, all the iodine passes into solution, while thallium and copper remain behind in the metallic state together with the zinc.

Oxygen-salts (Rammelsberg, *loc. cit.*) *Thallic acetate* is easily obtained in rather large crystals by dissolving freshly precipitated thallic oxide in strong acetic acid. The crystals belong to the rhombic system, and, according to Wilm, have the composition $Tl^3C^6H^6O^9$, which is that of a basic salt.

Thallious nitrate, $TlNO^3$, is isomorphous with the rhombic nitrates of the monatomic metals, such as potassium, ammonium, and silver nitrates.

Thallious perchlorate, $TlClO^4$, belongs to the rhombic system, and is isomorphous with potassium perchlorate.

Tri-thallic phosphate, like the corresponding lithium salt, is almost insoluble. *Di-thallic phosphate* was obtained by Lang in the anhydrous state, but its crystalline form is unknown; the hydrate, $2HTl^3PO^4 + aq.$ belongs, however, to the rhombic system. This latter salt agrees very closely in form with the salt $Na^3HPO^4 + aq.$ *Mono-thallic phosphate*, H^3TlPO^4 , and diammonium phosphate and arsenate, are isomorphous, and belong to the monoclinic system. From this it appears that in the three phosphates, R^3PO^4 , R^2HPO^4 , and R^3HPO^4 , H is isomorphous with R. The unequal hydration of the sodium salts disguises the isomorphism in this series. Thallium and potassium sulphates are also completely isomorphous, belonging to the rhombic system.

The double sulphates of thallium or potassium, with magnesium, zinc, nickel, or iron, are isomorphous; they belong to the monoclinic system. Thallium alum is also isomorphous with the ordinary alums.

Normal oxalate and bioxalate of thallium are crystalline, and belong to the monoclinic system; the quadroxalate is triclinic, and isomorphous with the corresponding potassium and ammonium salts.

Acid thallium tartrate is isomorphous with the potassium salt, and belongs to the rhombic system.

The double tartrates of thallium and sodium, and of thallium and antimony, are isomorphous with the potassium double salts. The picrates of thallium and of potassium and ammonium are, however, not isomorphous.

The ferrocyanides of thallium and rubidium are isomorphous, belonging to the triclinic system, and crystallising with 2 mols. of water.

On the Iodates and Periodates of thallium, see p. 683.

Thallious uranate is formed as a yellow precipitate resembling the uranates of the alkali metals, on adding thallious oxide to a solution of uranium (O. Bolton, *American Chemist*, 1872, ii. 456).

Double Salt containing Thallium and Platinum.—R. J. Friewell (*Chem. Soc. J.* [2], ix. 461) has obtained a salt having the composition $\text{PtCl}^2\text{Cy}^4\text{CO}(\text{Tio})^2$, by mixing hot solutions of potassio-platinous cyanide, $\text{PtK}^2\text{Cy}^4 + 3\text{H}^2\text{O}$ (4.334 grams), and thallious carbonate (9.360 grams), whereupon the following reaction takes place:

It may also be formed directly by mixing 7.094 grams of potassio-platinous cyanide with 4.680 grams of thallious carbonate (and the corresponding barium salt by mixing 4.384 grams of bario-platinous cyanide with 9.360 grams of thallious carbonate).

The potassic double salt forms rectangular prisms, exhibiting a splendid crimson colour by transmitted light and by reflection, a deep bronze-green colour with strong metallic lustre. It is sparingly soluble in hot, insoluble in cold water. The aqueous solution is absolutely colourless, and does not deposit the salt on cooling, unless it is very concentrated; it yields, however, white crystals which are either a hydrate or a mixture of the two component salts simultaneously separated. It is best recrystallised from a solution of thallium carbonate too dilute to deposit that salt on cooling. The aqueous solution does not exhibit absorption-bands. The salt heated with nitric acid gives off carbon dioxide and leaves a red residue of thallium platinumocyanide. By potassium iodide it is decomposed in the following manner:

THEBAICINE. An alkaloid, probably isomeric with thebaine and thebenine (*infra*), produced from the latter under the influence of strong acids, especially of hydrochloric acid. From the resulting solutions it is thrown down by ammonia, as an amorphous yellow precipitate, insoluble in ether, benzin, water, and ammonia, slightly soluble in hot alcohol, and separating again therefrom in the amorphous state. It dissolves in potash-ley, forming a solution which also absorbs oxygen. Strong nitric acid dissolves it with dark red, strong sulphuric acid with dark blue colour. Its salts are mostly resinous (Hesse).

THEBAINE, $\text{C}^{18}\text{H}^{21}\text{NO}^3$ (Hesse, *Ann. Ch. Pharm.* cliii. 47; *Bull. Soc. Chim.* [2], xiv. 73; *Gmelin's Handbook*, xviii. 208). This base, discovered by Thiboumery (v. 758), is one of the constituents of the precipitate obtained by treating the aqueous extract of opium with excess of sodium carbonate or lime, exhausting the filtered liquid with ether, agitating the ethereal solution with acetic acid, and pouring the acid liquid into an excess of moderately dilute potash- or soda-ley, taking care that the precipitate does not agglutinate. By dissolving this precipitate in acetic acid, treating it with animal charcoal, combining it with tartaric acid, recrystallising the tartrate from a small quantity of boiling water, and separating it with ammonia, the thebaine is obtained perfectly pure. In this state it crystallises from hot dilute alcohol in beautiful, colourless, crystalline leaflets; from strong alcohol in prisms. It melts at 193° and may be sublimed. It is tasteless; its salts have an alkaline reaction. It dissolves easily in alcohol, benzene, and chloroform, sparingly in ether (1:140), and is nearly insoluble in water. From the solutions of its salts it is precipitated by potash, ammonia, lime and bicarbonate of sodium; ammonia and lime dissolve it to a certain extent.

Thebaine, though a strong base, is easily decomposable; a solution containing excess of hydrochloric acid decomposes in a few hours. Strong nitric and sulphuric acids decompose it, producing a deep red coloration; dilute sulphuric acid converts it into thebenine and thebaicene.

Salts of Thebaine.—The hydrochloride, $\text{C}^{18}\text{H}^{21}\text{NO}^3\text{HCl} + \text{H}^2\text{O}$, forms large rhombic prisms. The platinumchloride, $2(\text{C}^{18}\text{H}^{21}\text{NO}^3\text{HCl})\text{PtCl}^4 + 4\text{H}^2\text{O}$, is obtained as

an amorphous yellow precipitate, which soon changes to beautiful prisms; the water of crystallisation (only half, according to Andersen) is given off at 100° . The *hydriodide*, obtained by adding potassium iodide to the tartrate, forms colourless prisms easily soluble in water. The *neutral oxalate*, $(C^{10}H^{11}NO^3 \cdot C^2H^2O^4 + 6H^2O)$, forms white, cauliflower-like masses, soluble in 9.7 pts. of water at 10° , easily soluble also in alcohol, insoluble in ether. The *acid salt*, $C^{10}H^{11}NO^3 \cdot C^2H^2O^4 + 11H^2O$, forms large colourless prisms soluble in 44.5 pts. of water at 20° . The *acid tartrate*, $C^{10}H^{11}NO^3 \cdot C^2H^2O^4 + H^2O$, forms delicate prisms, easily soluble in hot alcohol and hot water, slightly soluble in cold water (1 : 130 at 20°), having an acid reaction. The amorphous *neutral tartrate* is obtained by saturating the acid salt with thebaine, removing the excess of ether, and evaporating.

THEBENINE, $C^{10}H^{11}NO^3$ (Hesse, *Ann. Ch. Pharm.* cliii. 47; *Bull. Soc. Chim.* [2], xiv. 73). This base, isomeric with thebaine, is obtained by heating the latter (10 pts.) to boiling with hydrochloric acid (200 pts. of sp. gr. 1.04), and immediately mixing the liquid with an equal volume of cold water. The crystals of the salt, which separate after several days, are recrystallised from hot water, and the base is separated by treating the solution with sodium thiosulphate.

Thebaine is amorphous, insoluble in ether and in benzine, slightly soluble in boiling alcohol, insoluble in ammonia, soluble in potash, precipitated therefrom by sal-ammoniac, neutralises hydrochloric and sulphuric acids. It absorbs oxygen rapidly, especially when in contact with basic substances. With acids it is more permanent; nevertheless, its hydrochloride, heated for a few minutes to 100° with hydrochloric acid, is converted into thebaïne. Strong sulphuric acid dissolves thebaine with splendid blue colour, which disappears on addition of water, but is restored by further addition of sulphuric acid.

Thebaine hydrochloride, $C^{10}H^{11}NO^3 \cdot HCl + 3H^2O$, forms large crystalline laminae, easily soluble in boiling water and alcohol, sparingly in cold water (1 : 100), apparently not poisonous. The *platinochloride* is a brownish-yellow precipitate which quickly assumes a darker colour. The *mercurochloride*, $2(C^{10}H^{11}NO^3 \cdot HCl) \cdot HgCl^2 + 2H^2O$, crystallises in long colourless prisms mostly arranged in fan-shaped groups; effloresces in dry air. The *sulphate*, $(C^{10}H^{11}NO^3)_2 \cdot SO^4H^2 + 2H^2O$, separates on mixing the aqueous solution of the hydrochloride with sulphuric acid, as a white crystalline powder made up of prisms; it is nearly insoluble in cold and only slightly soluble in boiling water. The *acid oxalate*, $C^{10}H^{11}NO^3 \cdot C^2H^2O^4 + H^2O$, separates on adding oxalic acid to a hot solution of the hydrochloride, either as a crystalline precipitate or in satiny crystalline laminae, according to the degree of concentration. It is somewhat soluble in boiling water and crystallises therefrom in prisms.

THEBOLACTIC ACID. This supposed isomeride of lactic acid, obtained by T. and H. Smith from the mother-liquors of morphine (v. 759), has been examined by J. Y. Buchanan (*Deut. Chem. Ges. Ber.* iii. 182). By distilling 1 mol. of the calcium salt with 2 mols. PCl^5 , treating the portion of the distillate boiling above 111° with alcohol, and that which boiled below 111° with water, he obtained from the first portion chloropropionic ether, and from the second chloropropionic acid, both of which were found to be identical with the bodies similarly prepared from ordinary lactic acid. Hence Buchanan regards it as in the highest degree probable that the so-called thebolactic acid is nothing but ordinary lactic acid. It is optically inactive, and its copper salt (contrary to the statement of T. and H. Smith) does not differ in any respect from that of ordinary lactic acid.

THEBINE. See CAFFEINE (p. 230).

THELLITE. A supposed silicate of yttrium, from S. Paolo, Brazil, called by this name, consists, according to Phipson (*Chem. News*, xxi. 13), of 90.00 p.c. silica, 4.56 ferric oxide, alumina and glucina, and 4.54 water, without a trace of yttria. It is perhaps an impure quartz.

THERMO-REGULATORS. An automatic thermo-regulator for use in the preparation of nitrous oxide and other gases, is described by F. Clowes (*Chem. Soc. J.* [2], ix. 639). Another thermo-regulator is described by E. Reichert (*Pogg. Ann.* cxliv. 467).

THIOACETANILIDE. See THIOANILINE.

THIOALDEHYDE or **SULPHALDEHYDE**, $(C^2H^2S)^n$. The molecular weight of this compound has been determined by Hofmann (*Deut. Chem. Ges. Ber.* iii. 588) in the same manner as that of the thioaldehyde of the methyl series (p. 1155) viz. by means of the vapour-density. Two determinations made in xyline-vapour gave for n the value 3, the numbers found being 89.4 and 90.0, while calculation for

$\frac{1}{2}(\text{C}^2\text{H}^4\text{S})^2$ gives 90. Hence it would appear that the so-called thioaldehyde is really thioparaldehyde, analogous to paraldehyde, $(\text{C}^2\text{H}^4\text{O})^3$.

THIOAMYLIC ACID, $\text{C}^2\text{H}^4\text{SO}_2$. An isomeride of amylsulphuric acid, said by Commaille (*Compt. rend.* lxxv. 1630; *Jahresb. f. Chem.* iii. 581) to be obtained, together with 'parathionic acid,' from the mother-liquors of corallin (p. 391). On concentrating the mother-liquor, and heating it several times, till water no longer throws down any colouring matter, then boiling it with litharge, pouring the hot liquid into cold water, and filtering, the filtrate yields on concentration, first crystals of parathionate, and then of thioamylate of lead. Thioamyllic acid is described as crystallising more readily than amylsulphuric acid, and its salts as more permanent, the barium salt as crystallising in needles containing 1 mol. water, whereas the amylsulphate contains $2\text{H}_2\text{O}$ (v. 620). The ammonium, potassium and lead salts, as described by Commaille, differ more or less in crystalline form from the corresponding amylsulphates. As, however, the so-called parathionic acid has been shown to be not isomeric, but identical with ethylsulphuric acid (p. 897), it is not improbable that the slight differences between thioamyllic and amylsulphuric acids may be due to different degrees of purity.

THIOANILINE, $\text{C}^2\text{H}^3\text{N}^2\text{S} = (\text{C}^2\text{H}^3\text{NH})^2\text{S}$ (Merz u. Weith, *Deut. Chem. Ges. Ber.* iv. 384). When 2 mols. aniline and 1 mol. sulphur are boiled together in a retort with reversed condenser as long as hydrogen sulphide continues to escape, a thick oil is obtained consisting of thioaniline and unaltered aniline, together with a large quantity of resin, probably containing more highly sulphuretted anilines. To purify the product, the aniline is distilled off with vapour of water, the residue is boiled with dilute hydrochloric acid, the solution evaporated to dryness, the residue dissolved in water; a small quantity of alkali added to precipitate impurities, and then a larger quantity, which throws down the thioaniline as a yellowish oil, which solidifies to a crystalline mass. It is further purified by solution in ether-alcohol, and precipitation as sulphate with sulphuric acid. Better results are, however, obtained when litharge is added to the boiling mixture of sulphur and aniline; the reaction then takes place as follows:

and only a small quantity of resin is formed. The product is exhausted with boiling alcohol, and the residue, which contains the thioaniline, treated as before.

Thioaniline is sparingly soluble in cold, more easily in hot water, very easily in alcohol and ether. From hot water it crystallises, with previous turbidity, in long thin satiny needles, which melt in boiling water, and at 104° – 105° when dry; it decomposes when distilled, yielding aniline, hydrogen sulphide, and a coaly residue.

The salts of thioaniline have an acid reaction; their solutions, even when very dilute, stain a deal shaving with a fine orange colour. Chlorine-water colours the solutions brownish-red, and then separates brownish flocks. Potassium dichromate forms a violet precipitate soluble in alcohol. Platinic chloride separates black flocks gradually at ordinary temperatures immediately on heating. Thioaniline heated with strong sulphuric acid forms a red to blue or blue-violet solution, which when poured into water produces a fine red colour.

Thioaniline hydrochloride, $\text{C}^2\text{H}^3\text{N}^2\text{S} \cdot 2\text{HCl} + \text{H}_2\text{O}$, forms long colourless needles or shorter prisms easily soluble in water, less in alcohol, nearly insoluble in ether. The sulphate, $\text{C}^2\text{H}^3\text{N}^2\text{S} \cdot \text{H}_2\text{SO}_4 + \text{H}_2\text{O}$, crystallises from hot water in colourless shining prisms or spiculae, slightly soluble in cold water, nearly insoluble in ether and in alcohol. Ammonia added to the aqueous solution throws down, with partial decomposition, white nacreeous scales of a basic salt, $(\text{C}^2\text{H}^3\text{N}^2\text{S})^2\text{H}_2\text{SO}_4 + \text{H}_2\text{O}$.

The resin obtained in the preparation of thioaniline from sulphur and aniline has, after boiling with dilute hydrochloric acid, treatment with warm concentrated hydrochloric acid, and precipitation with water, the composition $\text{S}^2(\text{C}^2\text{H}^3\text{NH})^2 = 2\text{C}^2\text{H}^3\text{N}^2\text{S} + \text{S}$.

Thioacetanilide, $(\text{C}^2\text{H}^3\text{NH} \cdot \text{C}^2\text{H}_3\text{O})^2\text{S}$, is formed by the action of acetyl chloride or glacial acetic acid on thioaniline dissolved in benzene, as a crystalline mass easily soluble in hot, less easily in cold alcohol, slightly soluble in ether and in water, easily resolved by boiling dilute sulphuric acid into acetic acid and thioaniline sulphate. The product obtained with acetyl chloride melts at 213.5° , that prepared with acetic acid at 215° .

Thiosulphocarbaniilides.—When thioaniline is heated with carbon sulphide in alcoholic solution, hydrogen sulphide is evolved, and yellowish flocks are thrown down, which after washing with alcohol and ether, and boiling with carbon sulphide, consist of a mixture of two sulphocarbaniilides, viz.:

The mixture is microcrystalline, and melts with decomposition at a high temperature. Boiling concentrated sulphuric acid acts rather slowly on it, producing hydrogen sulphide, carbon dioxide, and thioaniline, but apparently no product analogous to mustard oil.

THIOBENZOIC ACID, $C^6H^4O^2S = C^6H^4(SH).COOH$. *Thiohydrobenzoic acid* (Hübner a. Upmann, *Zeitschr. f. Chem.* iii. 291).—This acid is produced by the action of nascent hydrogen (from tin and hydrochloric acid) on sulphobenzoic chloride (obtained by heating 1 pt. sodium sulphobenzoate with 2 pts. PCl^3):

The crystalline mass which separates is washed with hydrochloric acid, dissolved in ammonia, precipitated by hydrochloric acid, and recrystallised from hot alcohol.

Thiobenzoic acid is nearly insoluble in water, slightly soluble in alcohol, and crystallises from the latter in faintly yellowish needles, melting at 242° – 244° .

Ammonium thiobenzoate, $C^6H^4(SH)CO^+NH^4 + H^2O$, is a granulo-crystalline mass soluble in water and alcohol. The *barium salt*, $[C^6H^4(SH)CO^+]^2Ba + 2\frac{1}{2}H^2O$, is obtained by precipitating a boiling, very dilute solution of the ammonium salt with barium chloride, in small, white, prismatic needles. The *calcium salt*, $[C^6H^4(SH)CO^+]^2Ca + 3H^2O$, and the *lead* and *zinc* salts, are likewise obtained by precipitation.

When thiobenzoic acid is shaken up with 1 mol. bromine, hydrobromic acid is given off, and an acid is formed, probably dithiobenzoic acid, $(C^6H^4)^2S(CO^2H)^2$.

Metabromothiobenzoic acid, $C^6H^4Br(SH)COOH$, is obtained, similarly to the preceding, from bromosulphobenzoic acid. The crystalline mass separated by the action of tin and hydrochloric acid on bromosulphobenzoic chloride, dissolves for the most part in alcohol, and the solution when left to evaporate deposits the acid in small colourless needles melting at 264° – 266° , insoluble in water, easily soluble in alcohol.

THIOFORMALDEHYDE, $(CH^2S)^2$. *Methylene Sulphide*.—This body, first obtained by Girard by the action of nascent hydrogen on carbon sulphide (iii. 1007), is also produced by the action of sodium sulphide on methylene iodide (Huseman, *loc. cit.*), and by that of hydrogen sulphide on formaldehyde (Hofmann, 1st *Suppl.* 622). Its alcoholic solution mixed with silver nitrate yields a precipitate which, when washed with alcohol and dissolved in hot water, crystallises on cooling in thick rhombic laminae having the composition $(CH^2S)^2.AgNO^3 + H^2O$, and giving off their water at 100° . A solution of this salt in excess of silver nitrate yields $(CH^2S)^2.2AgNO^3 + \frac{1}{2}H^2O$, which also becomes anhydrous at 100° (Hofmann, *Deut. Chem. Ges. Ber.* ii. 152; iii. 584; Girard, *Compt. rend.* lxx. 625). The solution of the thioaldehyde boiled with platonic chloride yields a crystalline precipitate having, according to Hofmann, the composition $2C^6H^4S^2.PtCl^4$; according to Girard $2C^6H^4S^2.PtCl^3 + 2(C^6H^4S^2.PtCl^4)$.

Hofmann also finds that the precipitate sometimes contains platinous chloride, arising from partial reduction of the platonic chloride, but not in constant proportion. By mixing a solution of platinous chloride in hydrochloric acid with an alcoholic solution of thioformaldehyde, he obtained a light yellow precipitate having the composition $3C^6H^4S^2.2PtCl^3$.

From the preceding results, Hofmann infers that the molecular formula of thioformaldehyde is $C^6H^4S^2$, and this conclusion is confirmed by the vapour-density. Two determinations (in xylidine vapour) gave the values 72.0 and 73.2, the calculated value for $\frac{1}{2}C^6H^4S^2$ being 69.

According to Girard, thioformaldehyde, heated to 170° in a closed vessel with sulphate or borate of silver, is converted into dioxymethylene, $(CH^2)^2O^2$ (iii. 1006).

THIOHYDROBENZOIC ACID. Syn. with THIOBENZOIC ACID.

THIOISOPROPYL ALCOHOL, $CH(CH^3)^2SH$. Syn. with ISOPROPYL SULPHIDE (p. 1006).

THIOYL CHLORIDE, $SOCl$. See SULPHUR CHLORIDES.

THIOFARALDEHYDE. See THIOALDEHYDE (p. 1153).

THIOPHENOL, C^6H^4SH . *Phenyl Sulphydrate*, *Phenyl Mercaptan*.—This compound dissolves in cold sulphuric acid, with evolution of sulphur dioxide, forming a fine blue solution, which, on dilution with water, becomes colourless and deposits a reddish body having the composition $C^6H^4SO^3$:

The substance thus formed as an isomeric of benzene-sulphurous acid or phenyl-

sulphurous hydride (v. 564; 1st Suppl. 275), from which, however, it differs greatly in its properties (Brunner, *Deut. Chem. Ges. Ber.* iv. 984).

On the formation of Phenyl Bisulphite from thiophenol, see PHENYL SULPHIDES (pp. 941, 942).

THIORESORCIN, $C^6H^4S^2$. This compound is formed by the action of tin and hydrochloric acid on benzene-disulphonic chloride, $C^6H^4(SO^2Cl)^2$ (produced by treating the sodium salt of benzone-disulphonic acid [1st Suppl. 275] with phosphorus pentachloride). Thioresorcin melts at 27° and boils at 243° . Its alcoholic solution forms with lead acetate an orange-coloured precipitate, with copper salts a green, and with silver salts a light yellow precipitate (O. Pазебке, *J. pr. Chem.* [2], ii. 418).

THIOSULPHOCARBANILIDE. See THIOANILINE (p. 1164).

THIOUREA. A sulphuretted compound obtained as a secondary product in the preparation of leucinitril by Thudichum's method (p. 736).

THIOTOLUIDINE, $C^6H^4N^2S$ = $(C^6H^4NH)^2S$ (Menz a. Weith, *Deut. Chem. Ges. Ber.* iv. 384). This base is prepared, like thioaniline, by heating toluidine and sulphur together, with addition of litharge. It crystallises from alcohol in large colourless laminae resembling naphthalene, dissolves easily in ether and in alcohol, sparingly in water, whether cold or hot, melts at 103° to 103.5° . It unites easily with acids, forming well-crystallised salts which are decomposed by a large quantity of water, still retaining a strong acid reaction. The hydrochloride, $C^6H^4N^2S.2HCl$, crystallises in long, colourless, highly lustrous, anhydrous prisms. Platino chloride throws down from its concentrated solutions slender yellow needles of the salt, $C^6H^4N^2S.2HCl.PtCl_4$. The sulphate, $C^6H^4N^2S.H^2SO_4$, is thrown down by sulphuric acid from alcoholic solutions of the base, as a dazzling, white, anhydrous precipitate. It is decomposed by boiling water, with separation of the base, but crystallises from water acidulated with sulphuric acid, in wavelitic groups of needles containing 2 mols. water of crystallisation.

Hot concentrated sulphuric acid dissolves thiotoluidine, forming a solution which is nearly colourless at first, but afterwards becomes malaga-brown. Acid solutions of the base heated with oxidising agents (as ferric chloride, potassium dichromate, potassium chlorate, and hydrochloric acid, &c.) are coloured first yellow, then brown-red, then raspberry-red, and finally deposit dark coloured flocks. Chlorine-water, even in the cold, colours them deep yellow-red.

THYMOQUINONE, $C^6H^4(O^2)^2$. See THYMOL, under PHENOLS (p. 935). Lallemand's *thymid*, $(C^6H^4O^2)$, produced by mixing the alcoholic solutions of thymoquinone (thymoil) and thymohydroquinone (thymoilol), is in reality thymoquinhydrone, $C^6H^4O^2 = C^6H^4O^2$ (thymoquinone) + $C^6H^4(OH)^2$ (thymohydroquinone). See further, *Chem. Soc. J.* [2], ix. 350-354.

Bromothymoquinones (Carstanjen, *J. pr. Chem.* [2], iii. 50). When thymoquinone is heated with two molecules of bromine under water till the smell of bromine is no longer perceptible, a clear dark red oil is formed, which, after repeated washing with cold water, speedily solidifies to a hard yellowish-red crystalline mass, consisting of a mixture of mono- and di-brominated thymochinone.

Dibromothymoquinone, $C^6H^4Br^2(O^2)^2$.—The crystalline mass dissolves with tolerable facility in boiling alcohol, the solution depositing, as it cools, an abundance of fine, lustrous, pale yellow laminae, which are obtained perfectly pure by washing with cold alcohol. In the dry state this substance forms extremely light, shining, pale yellow laminae resembling chloranil. It melts to a pale yellow liquid at 73.5° . On exposure to light it gradually assumes a reddish colour. When it is treated with tin and hydrochloric acid, the group $(O^2)^2$ is converted into $(OH)^2$, the bromine being at the same time displaced by hydrogen, so that normal hydrothymoquinone is produced.

Monobromothymoquinone, $C^6H^4Br(O^2)^2$, is contained in the mother-liquor of dibromothymoquinone, and crystallises in long yellow needles on spontaneous evaporation of the solution; it has not, however, been obtained quite free from the dibromo-compound. The impure product dissolves with brownish-red colour in warm aqueous potash-ley; dilute acids throw down from the solution a yellow flocculent powder, which, after drying, sublimates in splendid scarlet crystals. This body is oxythymoquinone, $C^6H^4(HO)(O^2)^2$, the formation of which confirms the existence of monobromothymoquinone.

Oxythymoquinone, $C^6H^4(HO)(O^2)^2$ (Carstanjen, *loc. cit.*), is also obtained by distilling diamidothymol hydrochloride, $C^6H^4(HO)(NH^2)(HCl)$, with ferric chloride in a current of steam. The reaction in this case evidently resembles that observed by Grise and Ludwig in the case of diamidonaphthal (p. 831).

Oxythymoquinone crystallises from hot alcohol, in which it is easily soluble, in perfectly regular rhombic tables, the angles of which approximate to those of the cube, and from ether in irregular crystals having curved faces. It melts at 187° (uncorr.) in a capillary tube, and sublimes without decomposition in splendid glittering scarlet crystals.

As might be expected from the accumulation of electronegative groups, the hydrogen of the hydroxyl is not displaceable by acetyl, the substance being unacted upon by acetyl chloride. On the other hand, this hydrogen is readily displaced by basic radicals. Oxythymoquinone is converted by ethyl iodide at 100° into *ethoxythymoquinone*, $C^{10}H^{11}(C^2H^5O)(O^2)^2$, which sublimes completely in golden-yellow laminae. Aniline in alcoholic solution also acts immediately on a solution of oxythymoquinone; the liquid assumes a dark purplish-brown colour, and after evaporation the residue yields, by sublimation, beautiful violet needles having a brilliant metallic lustre, melting to a purple liquid above 200° and dissolving very freely in alcohol.

Oxythymoquinone is not easily acted on by reducing agents. On warming it with tin and hydrochloric acid, oxythymohydroquinone, $C^{10}H^{11}(OH)^2$, is produced. This body is a white crystalline mass, easily soluble in water, forming a solution which instantly turns yellow and deposits oxythymoquinone on exposure to air.

Dioxythymoquinone, $C^{10}H^{11}(HO)^2(O^2)^2$, is formed when dibromothymoquinone, moistened with alcohol, is dissolved in warm potash-ley, and the dark-brown solution is decomposed by dilute acids. The brownish-yellow flocks thereby thrown down, after being washed with hot water, dissolve in warm alcohol, which deposits crystals on evaporation, always contaminated, however, with a brown resinous substance, difficult to separate. The pure substance has not yet been analysed (Carstanjen).

TIGLIO ACID, $C^8H^8O^2$. An acid obtained from croton oil (p. 395).

TIN. *Disaggregation by Cold.*—Blocks of Banca tin, exposed to the air at St. Petersburg in the cold winter of 1867–68, swelled up, and acquired a fibro-crystalline structure, and were partly broken up into fragments of the same structure, partly crumbled to a granulo-crystalline powder. The cavities in the interior were lined with a metallically lustrous film, while the crystalline fragments themselves appeared dull (Fritzsche, *Pogg. Ann.* cxxvi. 176). A similar disintegration was observed in nearly pure block tin, containing only 0.3 p.c. foreign metals (lead and iron), which was sent from Rotterdam to St. Petersburg by rail during very cold weather in 1871 (Oudemans, *Instist.* 1872, 142).

According to F. Lewald (*Dingl. pol. J.* cxvii. 369) it is only block tin that disintegrates at low temperatures, the effect being due to the strong tension of the external parts produced by the previous casting and sudden cooling, this tension increasing as the temperature falls, and finally leading to disruption.

On a peculiar state of the molecules of tin, see further, Fritzsche (*Ann. Chim. Phys.* [4], xxvi. 321).

Specific Gravity.—Rammelsberg (*Deut. Chem. Ges. Ber.* iii. 724) found the specific gravity of the disintegrated tin described by Fritzsche to be 7.195; after fusion it rose to 7.310. The specific gravity of previously fused tin is, according to the accordant experiments of several observers, = 7.2905–7.299, whereas W. H. Miller (*Berg. Jahresh.* xxiv. 138) found, for tin deposited by electrolysis in quadratic crystals, a specific gravity = 7.178, which, however, rose after fusion to 7.293. Rammelsberg also found the specific gravity of tin reduced from stannous chloride by a feeble current to be 7.143 to 7.166, whence he infers that tin is dimorphous. After fusion it has a still undetermined, perhaps regular form, and in this form a specific gravity of 7.29; but by exposure to cold this form passes into a quadratic form, which the tin likewise assumes when reduced in the wet way, and in this form it has a specific gravity of 7.14–7.18. The decrease of volume of the last-mentioned form by heat is hereby explained.

The *specific heat* of tin, as determined by the ice-calorimeter (p. 595), is for cast-tin 0.559, for allotropic tin 0.546 (Bunsen).

Spectra.—The haloid compounds of tin impart to a hydrogen-flame a blue colour which may be ascribed to stannic oxide. The nucleus of this flame consists, however, of two concentric cylinders. The inner, which is nearly cold, is blue with chloride, green with bromide, yellow with iodide of tin, and always gives a continuous spectrum. It is surrounded by a somewhat warmer carmine-red sheath, the spectrum of which is reduced to a narrow bright line and an indistinct band, the former being near the second lithium line.* Bromide of tin in a cooled flame produces an emerald-green colour, with continuous spectrum (Salet, *Compt. rend.* lxxiii. 862; *Chem. Soc. J.* [2], ix. 1147).

* This is the colour first observed by Barrett (*Phil. Mag.* [4], xxx. 321).

Action of Nitric Acid.—G. Hay (*Chem. News*, xxii, 298) observes that pieces of tin about the size of pins' heads dissolve slowly at 2-2° in pure nitric acid diluted with an equal volume of water, forming a perfectly clear yellow solution which becomes colourless when gently heated and deposits metastannic hydrate on boiling. W. L. Scott (*ibid.* 322) states that he observed this fact some time ago, and adds that the separation of metastannic acid takes place at temperatures above 5°, or even lower, if the solution be exposed to a bright light.

Separation of Tin from other Metals.—To separate tin from arsenic and antimony, F. W. Clarke (*Zeitschr. anal. Chem.* ix, 487) boils the mixed solution with excess of oxalic acid, and passes hydrogen sulphide into the liquid to saturation. The arsenic and antimony are said to be thereby completely precipitated, while the tin remains in solution. To separate tin from molybdenum, the solution is mixed with excess of alkaline sulphide, the resulting sulphur salts decomposed with hydrochloric acid, and the precipitated sulphides of tin and molybdenum boiled with aqueous oxalic acid, which dissolves only the tin. If the tin was originally present as stannous salt, the resulting stannous oxalate must be dissolved in dilute hydrochloric acid.

To estimate the tin in the oxalic acid solution, ammonium is added in excess, then ammonium sulphide in sufficient quantity to redissolve the precipitate first produced, and finally the liquid is supersaturated with acetic acid, and left in a warm place. The resulting precipitate of stannic sulphide and oxide is washed with ammonium nitrate, ignited and weighed. According to G. C. Wittstein (*Zeitschr. anal. Chem.* ix, 490), the mode of separation just described is worthless, at least as applied to the separation of tin from arsenic and antimony, the precipitation of these two metals being very incomplete, and a considerable portion of the tin being precipitated with them.

For the separation of tin from antimony, see also p. 97.

The separation of tin from tungsten may be easily and completely effected by fusing a mixture of stannic and tungstic oxides with potassium cyanide in a porcelain crucible till the stannic oxide is reduced. The fused mass is lixiviated with water, the liquid filtered to separate the tin from the potassium tungstate, and the tin is washed with hot water, oxidised with nitric acid, and weighed as stannic oxide. The tungstic acid is best determined directly, after the potassium cyanide has been decomposed (J. H. Talbutt, *Deut. Chem. Ges. Ber.* iv, 279).

Chlorides. When chlorine not perfectly dry is passed over heated metallic tin, there is formed, in addition to anhydrous stannic chloride, a small quantity of a white crystalline sublimate having the composition $\text{SnCl}_4 \cdot 3\text{H}_2\text{O}$. If a very small quantity of water be added to this compound, or it be allowed to deliquesce, sulphuretted hydrogen precipitates the ordinary yellow stannic sulphide; but if it be dissolved in a large quantity of water, a yellowish-brown precipitate is produced by the same reagent. This may be attributed to the formation, by the excess of water, of metastannic chloride, from the solution of which the yellowish-brown metastannic sulphide is precipitated by sulphuretted hydrogen. Metastannic chloride is also produced when water is added to ordinary stannic chloride. This change is prevented by free acid, especially if water be not present in great excess. On dissolving several quantities of the same sample of tin in *nitro-muriatic acid*, and subsequently decomposing with sulphuretted hydrogen, stannic sulphide differing in colour was produced, probably in consequence of the formation of variable quantities of metastannic sulphide (H. Scheerer, *J. pr. Chem.* [2], iii, 47).

Chlorobromides.—When bromine is added by drops to stannous chloride, the violence of the reaction being moderated by cooling, it is found that to convert the whole of the stannous chloride into a stannic compound, 1 mol. bromine (Br_2) must be added for each molecule of SnCl_2 . The product is a yellow, strongly fuming liquid, having a very high specific gravity and easily decomposed by water. When distilled it begins to boil at 130°, the temperature slowly rising to 190°, at which the last drops pass over. Products of constant boiling point have not been obtained, but analysis showed that the higher-boiling portions were comparatively rich in bromine, the lower in chlorine, the reaction perhaps taking place as shown by the equation:

(Ladenburg, *Ann. Ch. Pharm., Suppl.* viii, 60).

Stannic Oxide and Acids. *Stannone* from the San Jacinto mine in San Bernardino, California, where it occurs in small grains and more rarely in larger crystals with topaz and quartz, has been analysed by F. A. Genth (*Chem. News*, xii, 334) with the following results:

SnO_2	WO_2	SiO_2	CaO	Fe_2O_3
88.00	1.08	7.20	0.32	0.40
79.15	0.22	9.52	0.27	13.84

Consisting of Fe, Mn, Al_2O_3 , H_2O , CaO, Fe_2O_3 , &c.

Twin crystals of tinstone from the granite veins of S. Piero, in Eiba, are described by G. vom Rath (*Jahrb. f. Min.* 1870, 890), who further remarks that only one other occurrence of tinstone in sporadic crystals of this kind is known, viz. at Chesterfield in Massachusetts.

A block of so-called 'Jew's tin,' or 'Jews'-house tin,' from Tremethack Moor in Cornwall, was found to be partially covered with a hard, brittle, brown crust, containing 90 p.c. stannic oxide, with small quantities of metallic tin, stannic chloride, ferric oxide, and silica. This crust somewhat resembles the native variety of stannic oxide called 'wood-tin,' and has probably been formed by the slow oxidation of the outer surface of the block (J. H. Collins, *Chem. News*, xxv. 271).

On the supposed crystallisation of stannic oxide from fused microcosmic salt, see PHOSPHATES (p. 976).

On the reaction of stannic oxide with phosphorous chloride, see p. 976.

Metastannic Acid.—According to A. H. Allen (*Chem. Soc. J.* [2], x. 274), the properties of this acid are somewhat different from those ordinarily assigned to it (v. 820). When the metastannic acid prepared by treating tin with nitric acid, and washing, is boiled for some minutes with a moderate quantity of strong hydrochloric acid (sp. gr. 1.11), a certain quantity of tin is dissolved, and, on adding a larger quantity of hydrochloric acid, almost complete dissolution takes place. The residue exhibits the properties commonly assigned to metastannic acid, excepting that its aqueous solution is less inclined to be precipitated by an excess of hydrochloric acid. The liquid poured into cold water gave at first a precipitate of stannic sulphate, but soon afterwards a precipitate of orthostannic acid. Commercial stannic acid (free from lead) dissolves only partially in strong sulphuric acid.

Stannates.—P. H. Vaughan (*Deut. Chem. Ges. Ber.* v. 396) prepares the stannates of the alkali-metals on the large scale by treating tin-clippings with caustic potash (or soda-loy) of sp. gr. 1.2, decanting the liquid, pumping air (or oxygen) through the vessels containing the metal, pouring the decanted solution again upon the metal, and repeating this treatment till the greater part of the alkaline liquid has been converted into a tin-solution. The reaction may be accelerated by gently warming the liquid and heating the air which is passed over the metal.

Compound of Stannic oxide with Acetic oxide.—When 2 pts. of acetic oxide and 1 pt. of metastannic acid, dried at 100°, are heated together for two or three hours to 150° in sealed tubes, a syrupy liquid is obtained, which solidifies, on cooling, to long needles having, when pressed and dried in a vacuum over quicklime, the composition $\text{SnO}_2 \left[\begin{smallmatrix} \text{C}^2\text{H}^3\text{O} \\ \text{C}^2\text{H}^3\text{O} \end{smallmatrix} \right] \text{O}$. After washing with pure ether and drying in a vacuum, the

crystals exhibit the composition $\text{SnO}_2 \left\{ \begin{smallmatrix} \text{C}^2\text{H}^3\text{O} \\ \text{C}^2\text{H}^3\text{O} \end{smallmatrix} \right\} \text{O}$. When exposed to the air, they are converted into an amorphous glassy mass having the composition $\text{SnO}_2 \cdot \text{C}^2\text{H}^3\text{O} \cdot \text{OH}$ (Laurence, *Compt. rend.* lxxiv. 1524).

TIN-RADICLES, ORGANIC. 1. **Stannethyls** (Ladenburg, *Ann. Ch. Pharm., Suppl.* viii. 60; *Deut. Chem. Ges. Ber.* iii. 353, 647). **Stannotriethyl iodide**, $\text{Sn}(\text{C}^2\text{H}^5)_3\text{I}$, is prepared by acting on 100 grams of sodium stannate containing 14 p.c. of tin with 80 grams of ethyl iodide in a flask provided with a reversed condenser, gentle heat being at first applied to set up the action, and the flask afterwards cooled to prevent it from becoming too violent. The mixture is afterwards heated in the water-bath, and finally to 150° in an oil-bath, and after the flask has cooled the contents are distilled in a sand-bath. In this way a product is obtained consisting of stannotriethyl iodide and stannotetethyl, which latter may be converted into stannotriethyl iodide by the action of hydriodic acid, just as the corresponding chloride is obtained by the action of hydrochloric acid (v. 832). This iodide, $\text{Sn}(\text{C}^2\text{H}^5)_3\text{I}$, boiling at 231°, is converted into **stannotriethyl** by the action of sodium, the flask containing it being connected with a reversed condenser by means of a Y-tube, through which the sodium is dropped. It is ultimately heated to 200°, and, after cooling, the stannotriethyl is separated from the sodium iodide by dry ether. On distilling off the ether, crude stannotriethyl remains as a liquid, boiling with partial decomposition at 265°–270°. It decomposes, with separation of tin, even when distilled in a current of carbon dioxide or hydrogen, but, by distilling it under a low pressure, it may be obtained pure.

Stannotriethyl is a liquid of sp. gr. 1.4115 at 0°, and having the pungent odour of the stannotriethyl-compounds; it is insoluble in water and in aqueous alcohol, and precipitates silver from an alcoholic solution of the nitrate. Two vapour-density determinations gave the numbers 14.70 and 14.93 ($H=1$), showing that the molecular formulae of the compound is not $\text{Sn}(\text{C}^2\text{H}^5)_3$, but $\text{Sn}^2(\text{C}^2\text{H}^5)_4$ (analogous to ethane) which remains to be proved.

Stannodiethyl chloride, $\text{Sn}(\text{C}^2\text{H}^5)_2\text{Cl}_2$, is obtained by passing chlorine into a solution of stannotriethyl in chloroform, or better in carbon tetrachloride, and remains, after evaporation of the solvent, in beautiful silky crystals which, after drying over sulphuric acid, melt at 85° (at 60° according to Cahours, v. 827). The *iodide*, $\text{Sn}(\text{C}^2\text{H}^5)_2\text{I}_2$, formed from it by precipitating with ammonia and dissolving the precipitate in hydriodic acid, melts, according to Ladenburg, at 44.5° (at 42° according to Frankland, v. 827).

The formation of stannodiethyl chloride from stannotriethyl and chlorine is represented by the equation:

To ascertain what might be the first mode of action of the halogen, Ladenburg added 1 mol. iodine to 1 mol. $\text{Sn}^2(\text{C}^2\text{H}^5)_3$, avoiding rise of temperature, and found that the action took place as shown by the equation:

The production of the compound, $\text{Sn}(\text{C}^2\text{H}^5)_2\text{I}_2$, by decomposition of stannotriethyl with iodine (Cahours, v. 829), is regarded by Ladenburg as doubtful. Stannotriethyl, treated with halogens, produces in fact only bodies of the type SnX_4 , the union between the two tin-atoms being first dissolved, and then the ethyl group replaced by halogens, a mode of action by which tin is essentially distinguished from carbon and silicon. Stannotriethyl, heated with strong hydrochloric acid, gives off inflammable gases, and an oil which solidifies, on cooling, to a mass which melts at 83° , and appears to be a mixture of $\text{Sn}(\text{C}^2\text{H}^5)_2\text{Cl}_2$ and $\text{Sn}(\text{C}^2\text{H}^5)_3\text{Cl}$, the former being produced according to the equation:

Stannotriethyl, treated with stannic chloride, yields stannotriethyl chloride and metallic tin:

Stannotriethyl ethylate, $\text{Sn}(\text{C}^2\text{H}^5)_2(\text{OC}^2\text{H}_5)_2$, is formed by the action of sodium ethylate on stannotriethyl iodide, the mixture being ultimately heated to 200° with reversed condenser, and then distilled out of contact with air. It is a colourless liquid having a very unpleasant odour, boiling at 190° – 192° , burning with a bright flame and separation of tin, and separating silver from an alcoholic solution of the nitrate. Sp. gr. = 1.2834 at 0° . Treated with iodine, it yields two compounds, one boiling at 240° , the other at a higher temperature. With water it forms crystals having the properties of the stannotriethyl hydrate described by Löwig & Cahours (v. 829). This hydrate boils at 269° – 273° , melts at 43° and changes when left over sulphuric acid, the melting point rising by nearly 100° (Ladenburg).

Stannomethyls. Ladenburg's observations on the stannomethyl-compounds differ considerably from those of Cahours (v. 832), according to which the action of methyl iodide on sodium stannide produces stannodimethyl or stannous methide, $\text{Sn}(\text{CH}_3)_2$, and stannotetramethyl or stannic methide, $\text{Sn}(\text{CH}_3)_4$. Ladenburg, following the directions given by Cahours, obtained, after distilling off the ether, only a few drops of residue (probably containing stanno-dimethyl), but found that the ether distilled off contained a compound which could not be purified by fractional distillation. He therefore altered the process so far as to heat sodium stannate, containing 14 p.c. of tin, with three-fourths of its weight of methyl iodide, first in the water-bath, then to 120° in the oil-bath, and afterwards in the sand-bath, and subject the product to fractional distillation, whereupon it separated into stannotetramethyl and stannotrimethyl iodide.

Stannotetramethyl or Stannic Methide, $\text{Sn}(\text{CH}_3)_4$, (freed from iodide by repeated fractional distillation over sodium) is a colourless liquid, having an ethereal odour, insoluble in water, boiling at 78° (at 140° Cahours), having a sp. gr. of 1.313 at 0° , and vapour-density, obs. = 6.00; calc. = 6.16.

Stannotrimethyl Iodide or Stannic Iodotrimethide, $\text{Sn}(\text{C}^2\text{H}_5)_3\text{I}$. This compound is obtained, more abundantly than by the process above described, by the action of 1 mol. iodine (I_2) on 1 mol. stannous methide, $\text{Sn}(\text{CH}_3)_2$. It is a liquid boiling at 170° and having a sp. gr. of 2.1432 at 0° , 2.1096 at 18° . (According to Cahours, it boils at 190° and has a sp. gr. of 2.155 at 18°). From silver nitrate it first throws down silver iodide, afterwards metallic silver.

Sodium acts on stannotrimethyl iodide according to the equation:

it is possible, however, that the compound $\text{Sn}^2(\text{CH}_3)_6$ may be formed in the first instance, and afterwards decomposed like the corresponding ethyl compound. The action of sodium ethylate on stannotrimethyl iodide produces a relatively small

quantity of stannotrimethyl ethylate, together with a large quantity of stannotetramethyl, from which mixture only the latter can be separated in the pure state.

TITANIFEROUS IRON. The following analyses of this mineral from Greensborough, North Carolina, have been collected by J. P. Lesley (*Proc. of the American Philosophical Society*, xii. 189): 1-3 by F. A. Genth; 4 by J. B. Britton; 5 and 6 by C. E. Buck; 7 and 8 by A. A. Fesquet.

* Insoluble matter mixed with the separated titanitic acid. Traces of sulphur in 4 and 6, of phosphorus in 7, of vanadium in 8.

The occurrence of titaniferous iron and magnesian iron ore in the Senfzergründel at Hinterhermsdorf in the Saxon Switzerland, is described by A. Stelzner (*Jahrbuch. f. Mineralogie*, 1871, 630). The several localities of *titaniferous magnetite sand* are enumerated by H. J. Buckart (*ibid.* ix. 421).

TITANIUM. On the Spectrum of titanium, see Troost a. Hautefeuille (*Compt. rend.* lxxiii. 620; *Chem. Soc. J.* [2], 1147).

On the separation of titanium from Niobium and Tantalum, see Rammelsberg (*Chem. Soc. J.* [2], x. 194).

Titanic Oxide or Anhydride, TiO_2 .—On the isomorphism of this oxide with stannic oxide, see G. Wunder (*J. pr. Chem.* [2], ii. 206).

Heated in an atmosphere of carbon monoxide, it gives up 4.7 p.c. oxygen, with separation of carbon (J. L. Bell, *Chem. News*, xxiii. 267).

On *Phosphotitanic acid*, see PHOSPHATES (p. 976).

Titanic Oxychloride, TiO_2Cl_2 = $\begin{matrix} Cl^+Ti-Ti=O \\ | \\ Cl^+Ti-Ti=O \end{matrix}$, is formed by the direct action of oxygen on titanitic chloride, $TiCl_4$ (Troost a. Hautefeuille, *J. pr. Chem.* [2], 4, 298).

TOBACCO. The physiological action of tobacco when used as a narcotic has been examined by Vohl a. Eulenberg (*Arch. Pharm.* [2], cxlvii. 130; *Chem. Soc. J.* [2], ix. 1075), with especial reference to the constituents of tobacco smoke. From the chemical history of tobacco they conclude that its action cannot be attributed to the narcotine which it contains, and this conclusion they confirm by analyses and experiments of their own.

The amount of nicotine in snuff was found to be only from .0392 to .062 p.c.; in the strongest tobacco for chewing there was only a trace of nicotine, and in other specimens of the same kind there was none at all, so that nothing like nicotine-poisoning can result from the use of these tobaccos.

The smoke of strong tobacco containing 4 p.c. of nicotine was also analysed, part of it being burned in a pipe and part as cigars. The smoke was drawn by an aspirator, first through potash-solution to collect acids, and then through dilute sulphuric acid to collect bases. Besides this, the gases given off when cigars were smoked were collected and examined. These consisted of oxygen, nitrogen, carbonic oxide, and marsh-gas.

The potash-solution was found to have absorbed hydrocyanic, sulphydric, formic, acetic, propionic, butyric, valeric and carboic acids; the presence of caproic, caprylic and succinic acid was doubtful. An oily liquid collected on the surface of the potash-solution, which solidified to a buttery mass, and this, when distilled, yielded at first a small quantity of hydrocarbons of the benzene-series, not, however, including benzene itself, and at higher temperatures a substance which solidified on cooling, and, after pressure and several recrystallisations from ether, had the form of viscerous scales melting at 64°-65°; it boiled above the range of the mercurial thermometer, and agreed in percentage composition, and in the characters of its picric acid compound, with the hydrocarbon $C_{10}H_{16}$, obtained by Kraus from wood-tar and examined by Fehling and by Fritzsche (*Jahrb. f. Chem.* 1858, 439, 440).

The dilute sulphuric acid was found to have absorbed the whole series of bases of

the pyridine series, viz. *pyridine*, C^4H^5N , *picoline*, C^4H^5N , *lutidine*, C^5H^6N , *collidine*, C^6H^7N , *parvoline*, C^6H^7N , *coridine*, C^6H^7N , *rubidine*, $C^{11}H^{12}N$, and *viridine*, $C^{12}H^{13}N$. When the tobacco is smoked in the form of cigars, the greater portion of the bases contained in the tobacco consists of collidine, which appears to be identical with the base called *aldehydine* by Baeyer (1st Suppl. 82). The most minute examination of the bases of tobacco-smoke failed to detect any trace of nicotine. All the volatile bases actually found, excepting ammonia and traces of ethylamine, belonged to the pyridine series; but it is possible that pyrrol bases may also be present.

The fact that very strong tobacco, which can scarcely be smoked in pipes, may be used for making cigars, is explained by the abundant occurrence of the highly volatile and intoxicating pyridine in pipe-smoking, whereas cigar-smoking produces only a small quantity of pyridine, but a large quantity of collidine. In general, pipe-smoking produces a larger proportion of the more volatile bases.

To determine the physiological action of the bases contained in tobacco-smoke, Eulenberg a. Vohl made experiments with pigeons and rabbits on the action of the more and less volatile picoline or pyridine bases from tobacco-smoke, from *Taraxacum officinale*, willow wood, and *Datura stramonium*. From these experiments it appears that all picoline bases are very poisonous, and differ from one another only in the rapidity and intensity of their action.

Vohl a. Eulenberg are of opinion that the disagreeable symptoms felt by persons beginning to smoke, and the chronic affections which occur in those who smoke to excess, as well as the cases of poisoning from swallowing tobacco-juice, are due, not to nicotine, but to the pyridine and picoline bases. The idea that they were due to nicotine originated in the fact that picoline bases having a high boiling point, such as parvoline, resemble that alkaloid greatly both in smell and in physiological action.

TOLANE, $C^{11}H^{10}$ (1st Suppl. 1099). This hydrocarbon is formed, together with barium sulphate, by heating barium benzoate with sulphur:

The tolane may be purified by repeated distillation over finely divided lead, or by heating its ethereal solution with lead or copper, and rectifying. It is also produced by heating a mixture of benzoate and sulphocyanate of barium (Pfankuch, *J. pr. Chem.* [2], iv. 35; vi. 113).

Tolane dissolves with brown colour in fuming sulphuric acid, and when heated, likewise in ordinary sulphuric acid, forming tolane-sulphonic acid, the barium and calcium salts of which are also brown, very soluble in water, and uncrystallisable. On heating either of these salts with potash, and adding hydrochloric acid to the fused mass, sulphurous oxide is evolved, and ether then extracts from the mass a brown oil containing benzoic acid and phenol (Limpricht a. Schwanert, *Deut. Chem. Ges. Ber.* iv. 379; *Jahresb. f. Chem.* 1871, 459).

Tolane Alcohol, $C^{11}H^{11}O^2$, is formed, together with benzoic, and acetic acids, by the action of alcoholic potash on acetyl-benzoïn, $C^{11}H^{11}(C^2H^3O)^2$ (i. 559). (Jena a. Limpricht, *Ann. Ch. Pharm.* clv. 89). It is not produced by fusing tolane-sulphonic acid with potash (Limpricht a. Schwanert).

Tolane Chlorides. *Tolane tetrachloride*, $C^{11}H^6Cl^4$, is formed by the action of phosphorus pentachloride at 200° on chlorobenzile, $C^{11}H^{10}OC^{11}$ (1st Suppl. 308). In boiling alcoholic solution it is easily converted by sodium-amalgam into tolane (Zinin, *Zeitschr. f. Chem.* [2], iv. 718). Treated in alcoholic solution with *sine*, it yields the two isomeric dichlorides, $C^{11}H^8Cl^2$, already described (p. 167), one melting at 153° , the other at 63° (Zinin). Limpricht a. Schwanert (*loc. cit.*) state that they have obtained the same two tolane dichlorides by heating 1 mol. tolylene (stilbene) to 170° with 2 mols. phosphorus pentachloride and a small quantity of the oxychloride. They confirm Zinin's statement respecting the melting points and solubilities of these bodies and their reactions with sodium-amalgam. They also find that both, when heated to 180° with alcoholic potash, yield tolane, together with potassium chloride; that their ethereal solution when evaporated leaves the compound $C^{11}H^8Cl^2$ unaltered; that each of these isomeric chlorides when distilled is partly converted into the other, a transformation which likewise takes place on heating them to 300° with glacial acetic acid and silver acetate, no acetyl-derivatives being thereby produced. Tolane treated with phosphorus pentachloride yields yellowish needles melting at 137° – 145° , and white glassy prisms melting at 150° , both of which appear, from the chlorine determination, to have the composition $C^{11}H^8Cl^2$ (Limpricht a. Schwanert).

Tolane Bromides. Tolane likewise forms with bromine two isomeric bromides, $C^{11}H^8Br^2$, one of which, crystallising in scales and melting at 200° – 203° , has already been described by Limpricht a. Schwanert (1st Suppl. 1099), the other, melting at 84° .

by Jena. Each of them, when heated to 170°–180° with water for several hours, is partly converted into the other. By distillation the modification melting at 64° is converted into that which melts at 200°–205°, whilst the latter, under the same circumstances, undergoes scarcely any alteration. By alcoholic potash or sodium-amalgam both modifications are converted into tolane. When continuously heated with water to 200° and above, both yield benzile, tolane, and hydrogen bromide. Heated to 120° with glacial acetic acid and silver acetate, they yield, together with benzile and tolane, white crystals of the compound $C^{11}H^{14}(C^2H^3O)Br$, melting at 107°; but if the temperature is allowed to rise to 140°–150°, the only products are benzile and tolane (Limpricht & Schwanert).

TOLIDINE, $C^{11}H^{14}N^1$. See next page.

TOLUENE, $C^6H^8 = C^6H^7.CH^1$. This hydrocarbon is formed in small quantity, together with products of higher boiling point, by heating potassium phenate with potassium acetate (Pfankuch, *J. pr. Chem.* [2], iv. 35).

Conversion into Cresol.—Toluene treated with sulphuric acid yields two isomeric tolueno-sulphonic acids, the potassium salts of which, when decomposed by melting potash, yield the corresponding cresols, one liquid, the other solid at ordinary temperatures, melting at 34.5°, and boiling at 202°:

(Wurtz, *Ann. Chim. Phys.* [4], xxv. 108).

Reaction with Iodine.—Toluene heated with iodine to 250° yields hydriodic acid, benzene, a hydrocarbon boiling at about 140° (xylene?), benzyltoluene, $C^{11}H^{14}$ (p. 183), and products boiling above 130°. The latter when distilled yield viscid hydrocarbons not yet examined, and a red solid residue, from which absolute alcohol extracts a red amorphous substance melting at about 100°, and having a composition represented by the formula $nC^{11}H^{11}$ (Schützenberger, *Compt. rend.* lxxv. 1767).

Azotoluene, $C^{11}H^{14}N^1$. This compound, discovered by Wergo & Jaworsky (1st *Suppl.* 285), has been further examined by F. Melms (*Deut. Chem. Ges. Ber.* iii. 549), who confirms the previous statements respecting its melting point, solubility, &c. It dissolves easily in fuming nitric acid, the solution after some time depositing small yellow crystals of a nitro-compound melting at 190.5°. It dissolves readily also in strong sulphuric acid, and is separated by water in its original state. It is soluble in water, alcohol, and dilute acids, but does not decompose carbonates. On mixing it with alkalis, the corresponding salts separate out, the sodium salt in yellow leaflets, the ammonium salt in yellow needles. Azotoluene is easily dissolved by bromine. By ammonium sulphide or sodium-amalgam it is converted into hydrazotoluene.

According to Petrieff (*Zeitschr. f. Chem.* vi. 264), nitric acid of sp. gr. 1.5, added to azotoluene in a cooled vessel, converts it into mononitro-azotoluene, $C^{11}H^{13}(NO^2)^1N^1$; but if added, without cooling, it forms trinitro-azotoluene, $C^{11}H^{11}(NO^2)^3N$ and trinitro-azoxytoluene, $C^{11}H^{11}(NO^2)^2N^2O$ (1st *Suppl.* 285).

Azoxytoluene, $C^{11}H^{14}N^2O$, is formed in small quantity, together with azotoluene, by the action of sodium-amalgam on nitrotoluene in alcoholic solution. According to Melms, the best yield of it is obtained by using only 6 pts. alcohol to 1 pt. of nitrotoluene. It crystallises, according to Melms, in yellow needles melting at 70°; according to Petrieff, in large red laminae melting at 57°. It is insoluble in water, dilute acids, and alkalis, easily soluble in alcohol and ether, decomposed by heat into azotoluene and toluidine. With strong nitric acid it forms nitro-derivatives. By strong sulphuric acid it is first dissolved, and afterwards partially decomposed. From its solution in fuming sulphuric acid, water throws down a red resinous mass. Bromine acts strongly on it, producing bromazoxytoluene, $C^{11}H^{13}BrN^2O$, which crystallises from them in small light yellow tablets melting at 74° (Melms).

Hydrazotoluene, $C^{11}H^{14}N^2$, is formed from azotoluene or azoxytoluene by the action of sodium-amalgam or ammonium sulphide. In contact with alcohol and air it is quickly reoxidised to azotoluene, and it is best prepared by heating azotoluene to 100° in sealed tubes with a saturated alcoholic solution of ammonium sulphide; it then separates in crystals which may be purified by washing with water (Melms).

Hydrazotoluene forms large colourless plates or needles, which melt at 124° and are resolved at high temperatures into azotoluene and toluidine. It is insoluble in water, easily soluble in alcohol, ether, and benzene; the solutions soon turn yellow from formation of azotoluene, and on addition of an acid this decomposition takes place immediately (Melms). By slow oxidation of an alcoholic solution of hydrazotoluene, azoxytoluene is produced as well as azotoluene (Petrieff).

Tolidine, $C^{11}H^{14}N^1$. This base, isomeric with hydrazotoluene, and homologous

with bensedine, $C^{12}H^{12}N^2$, is formed by the action of sulphurous acid on hydrazotoluene (Melms), or by dropping strong hydrochloric or sulphuric acid into an alcoholic solution of hydrazotoluene prepared with sodium-amalgam, the corresponding salt being then obtained; hydrazotoluene prepared with ammonium sulphide does not yield it (Petrieff). The free base forms colourless silvery laminae, easily soluble in boiling water, alcohol, and ether; melting at 128° – 129° , and decomposing when strongly heated (Petrieff). According to Melms, the crystals turn yellow or brownish on drying, and melt with brown coloration at 103° .

With sulphuric acid tolidine forms two salts, one soluble in hot water and alcohol, the other insoluble; the formula of the latter is $C^{14}H^{14}N^2 \cdot 2H^2SO^4$. The hydrochloride, $C^{14}H^{14}N^2 \cdot 2HCl$, is easily soluble in water, insoluble in hydrochloric acid, ether, and alcohol. Its aqueous solution forms, with platonic chloride, a yellow crystalline precipitate (Petrieff), dark red according to Melms. The picrate forms reddish-yellow needles (Melms).

Bromotoluenes. 1. *Monobromotoluene*, $C^8H^7Br \cdot CH^3$.—The para- and ortho-modifications of this compound, which are formed simultaneously by the direct action of bromine on toluene (1st Suppl. 280), have been further examined by Hübner a. Retschy (*Zeitschr. f. Chem.* [2], vii. 618).

Parabromotoluene is obtained by repeated crystallisation from alcohol, and careful pressure, in splendid crystals melting at 28° – 29° , and resolidifying at 28° ; it boils constantly at 185° – 2° . On dissolving it in 3 or 4 vols. of fuming sulphuric acid at a temperature not exceeding 80° , it yields two isomeric bromotoluene-sulphonic acids, which may be separated in the form of barium salts.

Orthobromotoluene.—To obtain this compound in the pure state, the crude liquid, forming about half of the total product of the action of bromine on toluene, was cooled down to -20° . On adding a few pieces of calcium chloride, some crystals of the para-compound separated. The liquid was poured off, and twice cooled down for some hours to -21° , when some more of the solid compound crystallised out. After seven fractional distillations, the liquid boiled at 183° – 2° , but it still contained a little of the para-compound, which was removed by acting on the liquid bromotoluene with a mixture of manganese dioxide, sulphuric acid, and glacial acetic acid, the parabromotoluene being oxidised to parabromobenzoic acid, whilst a part of the orthobromotoluene was completely destroyed, resembling in this respect orthonitrotoluene, which, like the bromo-compounds, does not give on oxidation a substituted benzoic acid.

Pure orthobromotoluene is a limpid liquid, boiling at 181° – 182° , not acted upon by sodium in the cold. On dissolving it at a gentle heat in Nordhausen sulphuric acid, it yields only one sulpho-acid.

Dmochowsky (*Deut. Chem. Ges. Ber.* v. 333) separates liquid from solid bromotoluene by repeatedly boiling the liquid expressed in the cold with chromic acid mixture as long as parabromobenzoic acid is thereby formed. There then remains a considerable quantity of liquid bromotoluene, which is not converted into an acid by oxidation.

Metabromotoluene is prepared from metabromotoluidine by Griess's method. The conversion of the metaluidine into diazotoluidine must be performed by small portions at a time, on account of the violence of the action. The liquid perbromide decomposed with alcohol yields metabromotoluene in the form of a liquid of sp. gr. 1.401 at 18° , boiling at 182° – 183° , and not solidifying at -20° . By oxidation with chromic acid it is converted into a resin from which no acid can be extracted. Bromine converts it into liquid dibromotoluene. It yields three sulpho-acids, distinguished as α , β , and γ (Wroblevsky, *Zeitschr. f. Chem.* [2], vii. 609).

Parabromotoluene dissolved in ether or in light petroleum oil is converted by sodium into ditolyl, $(C^8H^7)^2$ (Zincke, *Deut. Chem. Ges. Ber.* iv. 398; Longuinine, *ibid.* 614). Orthobromotoluene dissolved in light petroleum oil is not attacked by sodium at ordinary temperatures, but when a mixture of equal volumes of orthobromotoluene and petroleum oil is heated with sodium to 50° for about six days, toluene is formed, together with smaller quantities of crystals, and an oil distilling between 272° and 277° (Longuinine).

As sodium acts strongly at ordinary temperatures (15°) on parabromotoluene, but not on the liquid ortho-modification, it may be used to purify the latter from any portion of the solid modification that may remain in it after refrigeration. For this purpose the liquid bromotoluene, dissolved in three times its volume of petroleum oil, is treated at ordinary temperatures with sodium as long as the metal is thereby altered. Orthobromotoluene thus purified boils at 180° – 5° – 181° (Longuinine).

Orthobromotoluene, treated with sodium and methyl iodide, is converted into orthoxylylene (Jannasch a. Hübner, *Zeitschr. f. Chem.* [2], vii. 796).

Dibromotoluene, $C^H^4Br^2 = C^H^3Br^2.OH^1$. Several modifications of this compound have been obtained by Wroblevsky (*Zeitschr. f. Chem.* [2], vi. 239; vii. 136, 209, 271). Bromotoluidine from solid (para-) toluidine was converted into the azoperbromide, $C^H^4Br^2N^2Br^2$, and the latter was decomposed by alcohol. With alcohol of 80 p.c. orthobromotoluene was obtained; with alcohol of 94 p.c. the product consisted of three-fourths $C^H^4Br^2$, and one fourth $C^H^3Br^2$. The dibromotoluene, $C^H^4Br^2.Br.OH^1$, thus obtained is a liquid which does not solidify at -20° and boils at $238^\circ-239^\circ$. Sp. gr. = 1.812 at 19° . By nitration, it yields a nitrodibromotoluene, $C^H^4(NO^2)Br^2.Br^2$, which crystallises in beautiful needles melting at $86^\circ-87^\circ$, and when treated with tin and hydrochloric acid, is converted into a dibromotoluidine which crystallises in nacreous scales melting at 95° , and does not combine with acids.

Dibromotoluene, $C^H^4Br^2.Br^2$, obtained by brominating orthobromotoluene, remains fluid at -20° , boils at 236° , and has a sp. gr. of 1.8127 at 19° ; it is not oxidised by chromic acid. The nitrodibromotoluene obtained from it crystallises in needles, which melt at $86^\circ-87^\circ$, and yield a dibromotoluidine which separates in silky prismatic crystals melting at 83° . The same dibromotoluene is obtained by the action of absolute alcohol on the perbromide, $C^H^4Br^2.N^2Br^2$, from orthobromometatoluidine.

When the dibromotoluidines prepared from meta- and para-toluidine are introduced into alcohol saturated in the cold with nitrous acid, they are converted into isomeric dibromotoluenes. The reaction takes place in the cold, yielding nearly the theoretical quantity of dibromotoluene, together with aldehyde. The dibromotoluene thus prepared from metatoluidine is nearly insoluble in water and not very soluble in alcohol, melts at 42.5° and boils at 239° . By nitration it yields a dibromonitrotoluene, $C^H^4Br^2(NO^2)$, crystallising from alcohol, in which it is not very soluble, in beautiful needles melting at 59° . The dibromotoluene prepared from paratoluidine crystallises readily from alcohol in long needles, melts at 60° and boils at 241° . By nitration it yields a dibromonitrotoluene easily soluble in alcohol, and separating therefrom in prismatic needles which melt at 124° . These two dibromotoluenes are isomeric with that which Fittig obtained by direct action of bromine on toluene at ordinary temperatures (1st *Suppl.* 280), and with the two previously obtained by Wroblevsky (*supra*). Wroblevsky regards it as probable that the one obtained from paratoluidine has the orientation, 1 : 2 : 6; that from metatoluidine 1 : 2 : 5.

Dibromorthotoluidine, $C^H^4Br^2.(NH^2)_2$, yields, by elimination of NH^3 , a dibromotoluene, $C^H^4Br^2$, which has a sp. gr. of 1.812 at 22° , remains fluid at -20° , boils at 246° , and smells like monobromotoluene. By nitration it is converted into $C^H^4(NO^2)Br^2$, which crystallises from benzin in prisms melting at 79° .

All the six isomeric dibromotoluenes possible according to Kekule's orientation theory are therefore known; their properties are exhibited in the following table:

Dibromotoluenes.

	$C^H^4Br^2$	Melting point	Boiling point	Specific gravity	$C^H^4Br^2(NO^2)$ m. p.	$C^H^4Br^2(NH^2)$ m. p.
From toluene:	m-p 1 : 3 : 4	$107^\circ-108^\circ$	245°	—	—	—
From dibromo- paratoluidine:	o-o 1 : 2 : 6 (?)	60°	241°	—	124°	73° (?)
From dibromo- metatoluidine:	o-m 1 : 2 : 5 (?)	42.5°	239°	—	59°	50° (?)
From orthobro- motoluene and orthobromometa- toluidine:	o-m 1 : 2 : 3 (?)	Liquid	$238^\circ-239^\circ$	1.812 (at 19°)	$86^\circ-87^\circ$	83°
From dibro- mortho- toluidine:	m-m 1 : 3 : 5	Liquid	246°	1.812 (at 22°)	79°	92.5° (?)
From orthobro- moparatoluidine:	o-p 1 : 2 : 4	Liquid	237°	1.8127 (at 19°)	$86^\circ-87^\circ$	95°

Xedotoluene, $C^H^4I = C^H^3.I.OH^1$.—*Orthiodotoluene* is prepared from orthotoluidine by converting the nitrate of that base into diaxotoluene and decomposing the

latter with hydriodic acid. It is a light yellow liquid which boils at 205° , and has a sp. gr. of 1.697 at 20° . It is not converted into an acid by boiling with chromic acid. By nitration it yields two nitro-products, one solid, the other liquid. The solid modification forms small, thin, yellow needles melting at 98° – 99° (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* iii. 102).

By treating mercury-ditolyl with iodine, Dreher a. Otto (*Ann. Ch. Pharm.* cliv. 171) have obtained an iodotoluene different from the preceding and from that which Körner obtained by decomposing sulphate of diazotoluene (para-) with hydriodic acid (1st Suppl. 284). It boils between 200° and 210° , and solidifies in large rhombic plates smelling like anise, and melting a little above 20° . It dissolves easily in alcohol, ether, and carbon sulphide, and volatilises with vapour of water.

Chloriodotoluenes.—Wroblevsky (*Zeitschr. f. Chem.* [2], vi. 164) has prepared two isomeric compounds, C^7H^4ClI , from the diazo-derivatives of the two chlorotoluidines. α -Chloriodotoluene boils at 242° – 243° , has a sp. gr. of 1.716 at 17° , and does not solidify at -14° . β -Chloriodotoluene boils at 240° , has a sp. gr. of 1.770 at 19.5° , and solidifies at $+10^{\circ}$.

Para-iodo-orthobromotoluene, $C^7H^4I_2Br$, likewise prepared by Wroblevsky, by decomposing the diazo-compound of orthobromoparatoluidine, is a liquid which does not solidify at -14° , boils at 265° , and has a sp. gr. of 2.044 at 20° .

Nitrotoluenes (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2], v. 280, 521, 529; Rosenstiehl, *Ann. Chim. Phys.* [4], xxvii. 433–476). *Para*- and *orthonitrotoluenes* are obtained by the action of nitric acid (sp. gr. 1.475) on toluene. On submitting the product to distillation, the whole of that which passes over above 230° solidifies in the cold; this is *paranitrotoluene*. When purified by recrystallisation from alcohol it melts at 54° and boils at 235° – 236° (B. a. K.); melts at 52° and boils at 237° – 238° (Rosenstiehl). It is almost insoluble in water, but dissolves readily in alcohol, ether, and liquid nitrotoluene. When pure it is converted by the further action of nitric acid into dinitrotoluene, but when mixed with a large portion of the liquid modification, it is oxidised by nitric acid (Rosenstiehl).

Orthonitrotoluene.—According to Beilstein a. Kuhlberg, this liquid modification may be completely separated from *paranitrotoluene* by repeated rectification; according to Rosenstiehl the separation is never complete. Beilstein a. Kuhlberg also prepare this modification from dinitrotoluene by converting this base into nitrotoluidine, and the latter by treatment with nitrous acid in presence of alcohol (Griess's method) into mononitrotoluene. Orthonitrotoluene thus prepared boils at 222° – 223° , has a sp. gr. of 1.163 at 23.5° , agreeing therein with the liquid nitrotoluene prepared directly from toluene. According to Rosenstiehl, when purified as far as possible by fractional distillation, it still retains 8.76 p.c. of the solid modification, and the liquid so far purified boils at 219° – 220° . It is not oxidised by chromic acid mixture. It is the modification analogous in constitution to Rosenstiehl's pseudotoluidine.

Metanitrotoluene is prepared by Beilstein a. Kuhlberg as follows: When the acetyl-compound of solid toluidine (acetotoluidine) is added by small portions to well-cooled nitric acid of sp. gr. 1.475 as long as any action is perceptible, the liquid poured into snow, and the precipitate, after washing with water, repeatedly crystallised from hot water, nitroacetotoluidine, $C^7H^4(NO^2)(NH^2.C^2H^3O)CH^3$, is obtained in splendid lemon-yellow, glassy needles melting at 02° . By treating this compound with alcoholic potash, precipitating with water, and recrystallising from alcohol, γ -nitrotoluidine, $C^7H^4(NO^2)N$, is obtained in small red prisms melting at 114° . Lastly, by drenching this compound with strong nitric acid, passing nitrous acid into the liquid, and further treating it according to Griess's process, *metanitrotoluene* is obtained as a liquid having a sp. gr. of 1.168 at 22° , boiling at 230° – 231° , solidifying in a freezing mixture, and then melting at $+16^{\circ}$. By oxidation with chromic acid mixture it is easily converted into (ordinary) *metanitrobenzoic acid*.

Dinitrotoluene, $C^7H^4(NO^2)_2$.—By prolonged agitation of *metanitrotoluene* with very strong nitric acid, γ -dinitrotoluene is obtained in long, slender, colourless needles melting at 60° . 100 pts. of carbon sulphide at 16° dissolve 219 pts. of this body. Ordinary dinitrotoluene, formed by heating toluene with fuming nitric acid or treating it with a mixture of strong nitric and sulphuric acids (i. 575), has the same solubility, but melts at 70.5° .

Trinitrotoluene, $C^7H^3(NO^2)_3$, is obtained by boiling toluene with a mixture of fuming nitric and sulphuric acids. It forms white flat needles very much like dinitrotoluene, melting at 82° , easily soluble in ether and in hot alcohol, more easily in concen-

* Called in Beilstein a. Kuhlberg's paper *metanitrotoluene*; but the prefix 'meta' is there applied to 1 : 2 derivatives; 'ortho' to 1 : 3 derivatives.

posed by hot alkalis than the dinitro-compound (Wilbrand, *Ann. Ch. Pharm.* cxxviii. 178).

The same compound (b. p. 76° – 82°) appears to be obtained by boiling metanitrotoluene with fuming nitric and sulphuric acids; 100 pts. of carbon sulphide at 19° dissolve 0.236 pt. of it. By the action of ammonium sulphide it is converted into nitro-diamidotoluene or nitrotolylene-diamine, $C_6H_4(NO^2)(NH^2)_2$, and dinitrotoluidine, $C_6H_4(NO^2)_2NH^2$ (Beilstein a. Kuhlberg).

НИТРОБРОМОТОЛУЕНА, $C_6H_4Br(NO^2)$.—According to Wroblevsky a. Kurbatow (*Zeitschr. f. Chem.* [2], vii. 165), solid bromotoluene yields by nitration two isomeric nitrobromotoluenes. *α*-Nitrobromotoluene crystallises from alcohol in long needles, melts at 43° , boils at 256° – 257° , and yields a liquid bromotoluidine solidifying at -2° . *β*-Nitrobromotoluene is liquid, boils at 256° – 256° , does not solidify at -20° , has a sp. gr. of 1.631 at 18° , and yields a solid bromotoluidine melting at 67° .

Heynemann (*Zeitschr. f. Chem.* [2], vi. 402) obtains parabromometanitrotoluene, $C_6H_4Br(NO^2)$, by converting ordinary dinitrotoluene into nitrotoluidine, the nitrate of this base into diazotoluene by the action of nitrous acid, and decomposing the sulphate of diazotoluene with hydrobromic acid. It dissolves easily in ether and carbon sulphide, melts at 43° , boils at 256° – 257° , agreeing therein with Wroblevsky's *α*-nitrobromotoluene; but the parabromometoluidine prepared from it differs from Wroblevsky's *α*-bromotoluidine in being solid at ordinary temperatures, and melting at 30° . This bromotoluidine dissolves in 111.1 pts. of water at 17° .

НИТРОДИХЛОРОТОЛУЕНА, $C_6H_4(NO^2)Cl_2$, prepared by nitration of dichlorotoluene (b. p. 196° – 200°), solidifies completely at low temperatures like nitrobenzene, boils at 274° , and has a sp. gr. of 1.455 at 17° . By reduction it yields dichlorotoluidine, $C_6H_4(NH^2)Cl_2$, in dazzling white elongated laminae melting at 88° and boiling at 259° (Wroblevsky a. Pirogow, *Zeitschr. f. Chem.* [2], vi. 164).

НИТРОДИОДОТОЛУЕНА, $C_6H_4I_2(NO^2)$, or $C_6(CH_3)HHI(NO^2)H$, prepared like the corresponding bromine compound, is a faintly yellowish, well-crystallised compound, which dissolves easily in ether and carbon sulphide, melts at 60.5° – 61° , sublimes even at this temperature in slender capillary crystals, and begins to boil with decomposition at 286° . By reduction with tin and hydrochloric acid it is converted into paraiodorthotoluidine, which forms colourless needle-shaped crystals, melts at 48° – 49° , and boils with rapid decomposition at 273° (Heynemann, *loc. cit.*)

TOLUENESULPHONIC ACID, $C_6H_5SO^3 = C_6H_5\begin{Bmatrix} CH^3 \\ SO^3H \end{Bmatrix}$ (Engelhardt a.

Latschinoff, *Zeitschr. f. Chem.* v. 617; Anna Wolkow, *ibid.* vi. 321; *Jahresb. f. Chem.* 1870, 741). Two of these acids, the *para* or *α*, and the *ortho* or *β* modification, are formed by heating toluene on the water-bath with an equal weight of fuming sulphuric acid. They are separated by converting them into potassium salts, the *α* salt first crystallising out pure as the solution cools, and the mother-liquor on further concentration yielding a second crop of the *α*-salt mixed with nodules of the *β*-salt. Engelhardt a. Latschinoff separate these salts by sifting, the more soluble *β*-salt passing through with the mother-liquor. Wolkow picks out the crystals of the *α*-salt, recrystallises the remainder, again picks out the *α*-salt, &c., and finally recrystallises the nodular *β*-salt.

Tolueneparasulphonic Acid, $C_6H_4(CH_3)SO^3H$. The potassium salt, $C_6H_4KSO^3 + H^2O$, crystallises in large, long, six-sided tables and prisms, or by rapid cooling in long needles. It dissolves in hot alcohol and crystallises therefrom in needles; the crystals effloresce on exposure to the air (Engelhardt a. Latschinoff). On fusing it with potassium hydrate, and decomposing the mass with hydrochloric acid, it yields paroxybenzoic acid—as previously observed by Barth with crude toluene-sulphonate of potassium (*Deut. Chem. Ges. Ber.* ii. 523)—together with paracresol (Wolkow).

The other salts are prepared by liberating the acid with sulphuric acid, dissolving in alcohol, and neutralising. The sodium salt crystallises from alcohol in shining leaflets. The barium salt, $(C_6H_4SO^3)_2Ba$, is soluble in boiling alcohol, and crystallises therefrom in shining leaflets. The calcium salt crystallises from alcohol in needles. The lead salt dissolves easily in water, and crystallises in nodular groups of needles (Engelhardt a. Latschinoff).

Tolueneparasulphochloride, $C_6H_4(SO^2Cl)_2$, is obtained by heating the potassium salt on the water-bath with an equal weight of phosphorus pentachloride, treating the mass with water, and recrystallising the residuum from ether. It forms rhombic tables melting at 69° ; slowly decomposed by water, and is doubtless identical with the chloride previously described by Fittig, Märcker, Jaworsky, and Otto (v. 358).

Tolueneparasulphamide, $C^6H^4(SO^2NH_2)$, is formed by gently heating the chloride with strong aqueous ammonia. It crystallises from water and alcohol in shining laminae, melting at 137° . It possesses acid properties, dissolves in aqueous ammonia and potash more easily than in water, and is not decomposed by strong aqueous or alcoholic potash. When evaporated down with aqueous potash (1 mol. of the amide to 1 mol. KHO) it forms a compound which may be dissolved out by alcohol, and crystallises on evaporation in silky needles (Wolkow).

The *paratoluide* of the α -acid, $C^6H^4(SO^2NHC^6H^5)$, is formed by the action of the parasulphochloride on paratoluidine, these substances being heated together on the water-bath till the reaction is finished, the product boiled with water containing hydrochloric acid, and the residue crystallised from alcohol. It forms large shining crystals melting at 117° , and slightly soluble in water (Wolkow).

Tolueneparasulphobenzamide, $C^6H^4[SO^2NH(C^6H^5O)]$, is formed by the action of benzoyl chloride on tolueneparasulphamide at 150° – 160° . The product, purified by treatment with ether and recrystallisation from boiling alcohol, forms four-sided transparent flat prisms or needles, melts at 147° – 150° , dissolves easily in boiling alcohol, sparingly in cold alcohol, very sparingly in ether and in boiling water. The solutions have an acid reaction, and decompose carbonates. Silver nitrate and barium chloride form white precipitates with the ammoniacal solution. The *potassium salt*, $C^6H^4[SO^2NK(C^6H^5O)]$, crystallises from boiling alcohol in laminae. The *barium salt*, $(C^6H^5)^2[SO^2N(C^6H^5O)]^2Ba$, is slightly soluble in water, and crystallises therefrom in stellate groups of needles. The *calcium salt*, $(C^6H^5)^2[SO^2N(C^6H^5O)]^2Ca + H^2O$, crystallises in nodules easily soluble in water and in alcohol. The *silver salt*, $C^6H^4[SO^2NAg(C^6H^5O)]$, is a white precipitate nearly insoluble in water, easily soluble in ammonia. The ammoniacal solution when left to evaporate yields needles of the *argentammonium salt*, $C^6H^4[SO^2N(NH^4Ag)(C^6H^5O)]$, (A. Wolkow, *Zeitschr. f. Chem.* [2], vi. 577).

Tolueneparasulphobenzamide, treated with *phosphorus pentachloride*, is converted (by exchange of HO for Cl) into the chlorinated amide, $C^6H^4(SO^2NC^6H^5Cl)$, which crystallises from ether and melts at 100° . This chlorinated amide is converted by water into the original acid amide by exchange of Cl for HO, and by ammonium carbonate into the corresponding neutral amide, thus:

This neutral amide crystallises from alcohol, melts at 140° , is insoluble in water, aqueous ammonia, and alkaline carbonates; caustic alkalis dissolve it slowly, with evolution of ammonia (A. Wolkow).

Tolueneparasulphosuccinamides.—Tolueneparasulphamide treated with succinyl chloride yields two amides formed by the action of 1 mol. succinyl chloride on 1 or 2 mols. tolueneparasulphamide:

The first is an anhydride very slightly soluble in ether and crystallising therefrom in four-sided prisms. It unites with ammonia, forming the monobasic acid, $N^1(C^6H^4SO^2)(C^4H^3O^2)^1H$ or $C^6H^4O^2 \begin{matrix} \text{NH} - C^6H^4SO^2 \\ \text{NH}^2 \end{matrix}$, whose salts have the

composition $N^1(C^6H^4SO^2)(C^4H^3O^2)^1H^2M$. It unites also with water, forming the bibasic acid, $N^2(C^6H^4SO^2)(C^4H^3O^2)^2H^2O$, whose salts have the composition $N^2(C^6H^4SO^2)(C^4H^3O^2)^2M^2O$.

The second amide is a bibasic acid, which crystallises from hot alcohol in flat needles. Its solution in strong ammonia forms with *silver nitrate* and *barium chloride* white precipitates, containing respectively $(C^6H^4)^2(SO^2NAg)^2(C^4H^3O^2)$ and $(C^6H^4)^2(SO^2NBa)(C^4H^3O^2)$ (A. Wolkow, *loc. cit.*)

Toluenecorthosulphonic Acid (β -acid). The potassium salt of this acid, separated in the manner already described (p. 1167), is far from pure. It crystallises from alcohol in small laminae containing $C^6H^4(SO^2K) + 1\frac{1}{2}H^2O$, and when treated with phosphorus pentachloride yields the solid chloride already described and a liquid chloride. The former, heated with alcoholic potash, yields the α -potassium salt, the latter the β -salt, which crystallises from alcohol in laminae, and is converted by phosphorus pentachloride into the liquid chloride. Perfectly pure β -compounds can, however, be prepared only by decomposing the β -amide—which can be obtained quite free from the α -amide—with nitrous acid. The β -acid is thereby produced, and the salts may be prepared from it by neutralisation.

β -Toluenesulphonic acid belongs to the ortho-series.* Its potassium salt fused with potash yields salicylic acid, and a liquid cresol boiling in a stream of carbon dioxide at 188° – 190° (orthocresol, see 1st Suppl. 507). The β -potassium salt, $C^6H^4(SO^2K) + H^2O$, crystallises from water in nodules, from alcohol in shining plates which lose their water over oil of vitriol (Wolkow). The barium salt, $(C^6H^4SO^2)Ba + x aq.$, dissolves easily in boiling water and crystallises in nodules (Engelhardt & Latschinoff).

Toluene-orthosulphochloride, $C^6H^4(SO^2Cl)_2$.—This chloride, heated with benzamide, succinamide, and acetamide, yields the corresponding nitrils, together with toluene-orthosulphonic acid and hydrochloric acid; e.g.:

(A. Wolkow, *Zeitschr. f. Chem.* [2], vi. 421).

Toluene-orthosulphamide, $C^6H^4(SO^2NH^2)_2$, prepared from the chloride by the action of ammonia and recrystallised from hot alcohol, forms shining octohedral crystals, sparingly soluble in boiling water; it melts at 153° – 154° , and exhibits slightly acid properties. It dissolves in ammonia more readily than in water, also in aqueous potash, which does not decompose it at the boiling heat. Heated with boiling alcoholic potash, it yields the compound $C^6H^4(SO^2NHK) + \frac{1}{2}H^2O$, which crystallises in laminae (Wolkow).

Toluene-orthosulphobenzamide, $C^6H^4[SO^2NH(C^6H^5O)]_2$, is formed by the same process as the para-compound (p. 1168), but the yellowish syrupy product does not crystallise on cooling, but merely becomes thicker. To purify it, the mass is drenched with ether-alcohol, which dissolves it and converts the unaltered benzoyl chloride into benzoic ether; the crystalline mass remaining on evaporation is dissolved in sodium carbonate, and the solution, after being filtered to remove the benzoic ether, is precipitated with hydrochloric acid. The amide thus obtained forms a tenacious white precipitate which solidifies after a while to a crystalline mass. After washing with water and recrystallisation from ether, it forms transparent tablets and prisms, melting at 110° – 112° , slightly soluble in water, easily in alcohol and ether. Like the para-compound it reddens litmus and decomposes alkaline carbonates.

The *potassium salt*, $C^6H^4[SO^2NK(C^6H^5O)]_2 + \frac{1}{2}H^2O$, forms spherical groups of needles very soluble in water and in alcohol. The *barium salt*, $[C^6H^4SO^2N(C^6H^5O)]^2Ba + H^2O$, crystallises in flat prisms; the *calcium salt* is anhydrous and crystallises after strong concentration in spherical groups of needles easily soluble in water and in alcohol. The *silver salt*, also anhydrous, is a white precipitate sparingly soluble in water, freely in ammonia (A. Wolkow, *Zeitschr. f. Chem.* [2], vi. 57).

Paranitrotoluene-orthosulphobenzamide, $C^6H^3(NO^2)[SO^2NH(C^6H^5O)]_2$, is obtained by heating equivalent weights of β -nitrosulphotoluene-amide and benzoyl chloride to 145° – 150° as long as hydrochloric acid is given off. It crystallises in flat prisms grouped in stars, melts at 130° , and is readily soluble in boiling alcohol, but only sparingly in ether and boiling water. Its solution has an acid reaction, and decomposes alkaline carbonates. The *potassium salt*, $C^6H^3(NO^2)[SO^2NK(C^6H^5O)]_2$, is anhydrous, readily soluble in water and alcohol, and forms warty needles. The *barium salt* is insoluble in alcohol, sparingly soluble in water, and forms needles grouped in stars. The *calcium salt* crystallises from water and alcohol in nodules. The *silver compound* is a precipitate drying up to a horny mass, slowly attacked by boiling with hydrochloric acid (A. Wolkow, *ibid.* 422).

This amide, heated to 145° – 150° with phosphorus pentachloride, is converted (by exchange of HO for Cl) into the chlorinated amide, $C^6H^3(NO^2)(SO^2NC^6H^4Cl)$, which dissolves sparingly in boiling ether, and crystallises therefrom, melts at 122° – 123° , and dissolves slowly in aqueous alkalis, with evolution of ammonia.

Toluenemetasulphonic Acid, $C^6H^4(SO^2H)_2$, is prepared by the action of sodium-amalgam on the sodium salt of the bromotoluenesulphonic acid obtained by treating crude bromotoluene with strong sulphuric acid, after it has been freed from solid bromotoluene. The liquid, after six days' action, is saturated with sulphuric acid; the greater part of the sodium sulphate removed by concentration; the mother-liquor evaporated to dryness; the residue treated with phosphorus pentachloride; and the resulting toluenesulphochloride is washed and decomposed by heating it with water to 130° . On evaporating the resulting solution till the temperature rises to 110° , and passing a rapid stream of air through it at this temperature as long as hydrochloric acid continues to escape, metatoluenesulphonic acid remains as a brownish syrup which

* In the original memoir it is said to be a meta-compound; but at the time when that memoir was published (1870), salicylic acid was also regarded as belonging to the meta-series.

solidifies to a crystalline mass on cooling. The following salts are extremely soluble in water and alcohol, and agree in their amounts of crystallisation-water with the corresponding bromotoluenesulphonates:

$C^6H^5SO^3K$	$+ \frac{1}{2}H^2O$	Highly lustrous laminae, resembling naphthalene.
$C^6H^5SO^3Na$	$+ \frac{1}{2}H^2O$	Crystallises from alcohol in large, shining laminae.
$(C^6H^5SO^3)^2Ba$	$+ 2H^2O$	Non-crystalline powder.
$(C^6H^5SO^3)^2Ca$		Separates from alcohol in small shining tablets.
$(C^6H^5SO^3)^2Pb$	$+ 2H^2O$	Separates from water in rosettes of laminae; from absolute alcohol in long needles, and is precipitated from the alcoholic solution by ether in small shining tablets. Gives off its water at 130° , and is then very hygroscopic.

Metatoluenesulphochloride, $C^6H^5SO^3Cl$, prepared from the potassium salt by the action of phosphorus pentachloride, is a clear faintly-yellow liquid, having a pungent odour, not solidifying at -10° , insoluble in water, easily decomposed by heating it with water in a sealed tube to 130° .

Metatoluene sulphhydrate, C^6H^5SH , formed by the action of tin and hydrochloric acid on the sulphochloride, is a limpid, strongly refracting liquid, having a powerful odour, and exerting a caustic action on the skin. It does not solidify at -10° , is insoluble in water, easily soluble in alcohol, dissolves sulphur and iodine, and forms sparingly soluble compounds with metals.

Metatoluene disulphide, $(C^6H^5)_2S^2$, produced by boiling the sulphhydrate for several days with strong nitric acid, is a yellowish oil which remains fluid at -12° , boils, with decomposition, at about 150° , is insoluble in water, but easily soluble in alcohol, ether, and xylene. Strong nitric acid converts it into a brown resinous mass.

Metatoluenesulphamide, $C^6H^5SO^3NH^2$, obtained by boiling the chloride with aqueous ammonia, evaporating, and exhausting with ether, is a crystalline body moderately soluble in cold, easily in boiling water, very easily in alcohol, ether, and ammoniacal water. From a slightly concentrated solution it crystallises at low temperature in small threadlike forms, from a more concentrated solution at 30° in transparent, colourless tables of the size of a square inch; if the temperature falls below 20° , the first form appears. Melts at $91^\circ-92^\circ$.

The above-described characters of this sulpho-acid and its derivatives, especially of the chloride and amide, show that it is quite distinct from para- and ortho-toluenesulphonic acid, and must therefore be the meta-compound.

Toluenedisulphonic Acid, $C^6H^4(SO^3H)^2 = C^6H^4 \begin{pmatrix} OH^+ \\ (SO^3H)^- \end{pmatrix}$ Senhofer

(*Ann. Ch. Pharm.* cxliv. 126) obtains an acid of this composition by heating toluene with Nordhausen sulphuric acid and phosphorus pentoxide for four or five hours to 230° . On opening the tubes a large quantity of sulphur dioxide is evolved. The brown residue is dissolved in water, and the solution is boiled and neutralised with barium carbonate. By adding alcohol to the concentrated filtrate, the *barium salt* is obtained as a white precipitate, having the composition $C^6H^4(OH^+)(SO^3)^2Ba + 3\frac{1}{2}H^2O$. The *potassium salt* is produced by adding milk of lime to a solution of the crude acid and precipitating the calcium salt with potassium carbonate. By recrystallisation, it is obtained in short, well-defined prisms, having the composition $C^6H^4(OH^+)(SO^3)^2K^+ + H^2O$.

By decomposing the barium salt with sulphuric acid, evaporating the filtrate, and exhausting the residue with a mixture of alcohol and ether, a solution of the *free acid* is obtained, crystallising in a vacuum over sulphuric acid in soft microscopic needles.

The *silver salt*, $C^6H^4(OH^+)(SO^3Ag)^+ + 2H^2O$, is formed by neutralising a boiling solution of the acid with silver oxide; it forms yellow crystals. The *cadmium salt* is a gum-like mass; the *ammonium salt* forms very soluble needles.

By fusing the potassium salt with potash, salicylic acid and isoeurin, $C^6H^3O^4$, are produced. The latter compound melts at 87° , boils at 260° , and solidifies on cooling to a radiate crystalline mass. It has a faint sweet taste, and dissolves in water, alcohol, and ether. Isoeurin has great resemblance to orcin, from which, however, it

differs by its reactions. Its solution does not assume a red colour when exposed to the air; with ferric chloride it yields a brownish-green colour; it reduces ammoniacal silver solutions even in the cold, and gives, with bleaching powder, a red colour changing gradually into yellow. In presence of ammonia and air it acquires a brown colour, but becomes colourless again on addition of acetic acid.

Potassium toluenedisulphonate, fused with sodium formate, is converted into the potassium salt of isoxylidic acid, $C^6H^4(CH^3)(CO^2H)^2$. This acid is almost insoluble in cold water, sparingly soluble in hot water, but readily in alcohol and ether, and forms microscopic crystals. When heated, it begins to soften at 280° , but melts only completely at 375° . By sublimation it is obtained in yellowish well-defined needles. The barium salt, $C^6H^4(CH^3)(CO^2)Ba + 2H^2O$, is a yellowish crystalline mass; the silver, lead, cadmium, and copper salts are amorphous precipitates.

Two other toluenedisulphonic acids (α and β) have been obtained by P. Hakansson (*Deut. Chem. Ges. Ber.* v. 1084), by heating toluenemonosulphonic acid (which ?) with fuming sulphuric acid to about 160° . Both appear to differ from Senhofer's acid (γ -acid). The following are the chief points of difference between the α - and β -acids.

α -Toluenedisulphonic chloride, $C^6H^4(SO^2Cl)^2$, crystallises from ether in large four-sided prisms, which melt at 51° – 52° ; the β -chloride is less soluble in ether, has apparently a different crystalline form, and melts at 94° . The α -amide, $C^6H^4(SO^2NH^2)^2$, crystallises in thin long prisms which melt at 186° ; the β -amide is less soluble in water and melts at 216° . The α -chloride, boiled with an alkaline sulphite, yields toluenedisulphonic acid, $C^6H^4(SO^2H)^2$. The α -acid, fused with potash, yields, together with salicylic acid and small quantities of paraoxybenzoic acid, a body having the composition $C^7H^5O^4$, but differing in its properties both from ordinary orcin and from Senhofer's isocin.

The α -acid, fused with sodium formate, yields a small quantity of a *toluene-dicarboxylic acid*, $C^6H^4(CO^2H)^2$, in the form of white difficultly soluble flocculi, which exhibit signs of melting below 270° , but are at the same time carbonised.

The potassium salt of the α -disulpho-acid, digested with chromic acid mixture, is slowly oxidised and converted into α -disulphobenzoic acid, $C^6H^4(CO^2H)(SO^2H)^2$, which is different from the acid obtained by Barth & Senhofer directly from benzoic acid (*Ann. Ch. Pharm.* clix. 217); it yields a highly characteristic, difficultly soluble, acid potassium salt, $C^6H^4(CO^2H)(SO^2K)^2 + H^2O$, which is precipitated on the addition of hydrochloric acid to a solution of the normal potassium salt, $C^6H^4(CO^2K)(SO^2K)^2 + 2H^2O$.

Bromotoluenesulphonic Acids. $C^6H^4Br.SO^2H$. Hübner & Retzsch (*Zeitschr. f. Chem.* [2], vii. 618; *Jahresb. f. Chem.* 1871, 501).

I. From Crystallised Parabromotoluene.—Hübner & Post (*Zeitschr.* vi. 390; *Jahresb.* 1870, 746) describe three isomeric sulpho-acids obtained by dissolving parabromotoluene in fuming sulphuric acid; but Hübner & Retzsch find that, as theory requires, only two distinct sulpho-acids are thus produced, viz.:

α . Parabromotoluene-orthosulphonic acid	C^6	CH^3	SO^2H	H	Br	H	H
β . Parabromotoluene-metasulphonic acid	C^6	CH^3	H	SO^2H	Br	H	H

These acids are prepared by dissolving 1 vol. pure parabromotoluene in 3 to 4 vols. fuming sulphuric acid, with agitation, and heating to a temperature not exceeding 80° . The characters of their salts and derivatives are as follows:

(1). α -series (Hübner & Post's γ -series). The barium salt, $(C^6H^4Br.SO^2)Ba + 7H^2O$, crystallises in long well-defined needles which do not become opaque by being left in the mother-liquor, or by exposure to sunshine. The lead salt, $(C^6H^4Br.SO^2)Pb + 3H^2O$, separates at first in long pointed needles, but, after repeated crystallisation, it is obtained by slow evaporation in groups of light-yellow, well-defined rhombic crystals which preserve their lustre unaltered even after prolonged exposure over sulphuric acid. The strontium salt, $(C^6H^4Br.SO^2)Sr + 7H^2O$, forms small rather hard crystals acid. The amide, $C^6H^4Br.(SO^2NH^2)$, prepared up of two four-sided irregular pyramids. The amide, $C^6H^4Br.(SO^2NH^2)$, prepared from the corresponding chloride $C^6H^4Br.(SO^2Cl)$, crystallises in soft needles nearly an inch long, perfectly colourless, having a silky lustre, and united in groups having exactly the appearance of a fan-shaped palm-leaf. It dissolves sparingly in cold, easily in hot water, also in alcohol and in ether. Melts at 151° – 152° .

(2). β -series. The barium salt, $(C^6H^4Br.SO^2)Ba + H^2O$, crystallises very slowly from the cold saturated solution in hard whetstone-shaped crystals, apparently composed of thick rhombic prisms grouped in rosettes. From the hot solution the salt separates as an apparently amorphous mass; but on dissolving this mass in a large quantity of water, it crystallises, by slow cooling, in large, soft, flexible, silvery laminae, apparently belonging to the rhombic system. 1 pt. of this salt requires for solution

186 pts. of water at 8°. The lead salt, $(C^6H^5BrSO^3)^2Pb + 3H^2O$, separates gradually from its cold solution, after several hours' standing, in stellate groups of small needles which, when once formed, rapidly grow into arborescent forms. At low temperatures the salt separates very quickly in larger groups of fine soft needles; they have a satiny lustre, but when exposed to the air quickly lose part of their water and become dull. The calcium salt, $(C^6H^5BrSO^3)^2Ca + 4H^2O$, crystallises in thin laminae, or sometimes in groups of three-sided tablets with truncated summits. The crystals are rather hard and shining, and when left over sulphuric acid, give off part of their water and become dull.

β -Parabromotoluenesulphamide, $C^6H^4Br(SO^2NA^2)$, melts at 166°–167°, and crystallises from water in long shining slender needles.

II. *Orthobromotoluenesulphonic acid*.—Pure liquid bromotoluene was converted, by agitation and careful warming with fuming sulphuric acid, into the sulphonic acid, and this into the barium salt, $(C^6H^4BrSO^3)^2Ba + 2H^2O$, which crystallises in large soft elongated plates; no isomeric salts were found in the mother-liquor. 1 pt. of the barium salt dissolves in 253 pts. at 17°. The calcium salt, $(C^6H^4BrSO^3)^2Ca$, crystallises very slowly from a highly concentrated solution in thick rhombic tables, becoming hexagonal by truncation of their acute angles, and grown together by their edges. It has an extraordinary lustre, is anhydrous, and remains perfectly transparent after being heated to 186° for six hours. It is very soluble in water. The lead salt, $(C^6H^4BrSO^3)^2Pb + 2H^2O$, forms tufts of long narrow tables, and is much more soluble than the barium salt. The potassium salt, $C^6H^4BrSO^3K + \frac{1}{2}H^2O$, forms small, thick, rather hard, white needles, moderately soluble in water. The sodium salt, $C^6H^4BrSO^3Na + \frac{1}{2}H^2O$, crystallises in large thick rhomboidal tables with truncated edges, and is very soluble in water.

Orthobromotoluenesulphonic acid is converted, by oxidation with potassium dichromate and dilute sulphuric acid, into orthobromosulphobenzoic acid (Hübner a. Retschy).

According to Dmochowsky (*Deut. Chem. Ges. Ber.* v. 333) pure orthobromotoluene, treated with fuming sulphuric acid, yields two sulphonic acids which yield barium salts containing $(C^6H^4BrSO^3)^2Ba + 2H^2O$, one sparingly soluble in water, the other easily soluble. Both acids, when fused with potash, yield salicylic acid.

III. *Metabromotoluenesulphonic acids* (Wroblevsky, *Zeitschr. f. Chem.* [2], vii. 6).—When fuming sulphuric acid is added to cooled metabromotoluene, the reaction completed by warming in the water-bath, and the product saturated with baryta, three barium salts (α , β , γ) are formed which may be separated by fractional crystallisation. The β -salt forms the largest portion of the product, next the α -salt (about 25 p.c.) and of the γ -salt only a small quantity is obtained (3 p.c.)

The α -barium salt, $(C^6H^4BrSO^3)^2Ba + H^2O$, crystallises in small prisms; 1,000 pts. of water at 19° dissolve 5.28 pts. of it. The α -potassium salt crystallises in small prisms. By fusion with potash it yields salicylic acid: hence the α -acid is metabromotoluene-orthosulphonic acid, $C^6H^4Br(SO^3H)$.

The β -barium salt, $(C^6H^4BrSO^3)^2Ba + 3H^2O$, crystallises in beautiful shining laminae. 1,000 pts. of water at 19° dissolve 14.52 pts. of this salt. The β -lead salt, $(C^6H^4BrSO^3)^2Pb + 3H^2O$, forms large prisms. The β -calcium salt, $(C^6H^4BrSO^3)^2Ca + 5H^2O$, crystallises easily in large prismatic laminae. The β -potassium salt crystallises in large shining laminae. This salt also yields by fusion with potash, a considerable quantity of salicylic acid, so that the β -sulpho-acid is likewise a metabromotoluene-orthosulphonic acid.

The γ -barium salt, $(C^6H^4BrSO^3)^2Ba + 5H^2O$, crystallises in needles. 1,000 pts. of water at 19° dissolve 32.48 pts. of it. By fusing the γ -potassium salt with potash, an oxy-acid was obtained, which did not colour ferric salts: therefore either oxybenzoic or para-oxybenzoic acid.

The following table, on p. 1173, gives a comparative view of the properties of the three bromotoluenes and of their sulphonic derivatives.*

Chlorotoluenesulphonic Acid, $C^6H^4Cl(SO^3H)$. Two acids (α and β)

having this composition are produced by heating chlorotoluene with sulphuric acid; their barium and potassium salts have been already described as chloro-cresylsulphites (p. 878). The α -cadmium salt, $(C^6H^4ClSO^3)^2Cd + 2H^2O$, crystallises in flat needles.

* This table is taken from Hübner a. Retschy's paper (*Zellisch. f. Chem.* [2], vii. 681). It will be observed that the quantities of water here assigned to the β -Ba- and α -Ba- salts of the β -meta-acid and to the β -Ba-salt of the γ -acid are only half those ascribed to them by Wroblevsky (*supra*). In a note to the abstract of Hübner a. Retschy's paper in the *Abstract. f. Chem.* 1874, 566, it is stated that these quantities of water given by Wroblevsky have been corrected in a subsequent paper in the same volume of the *Zellisch. f. Chem.* (p. 768). This reference is incorrect, as the said volume (1874) contains only 786 pages. Moreover, the correction in question is not to be found in any other paper by Wroblevsky contained in the same volume.

Bromotoluenes and their Derivatives.

easily soluble in water and in alcohol. The α -potassium salt fused with potash yields orcin (Vogt a. Henniger, *Ann. Chim. Phys.* [4], xxv. 129).

Two *chlorobenzylsulphurous acids*, C⁶H⁴.Cl{CH²Cl
SO²H}, metameric with the preceding, are formed by boiling chlorobenzoyl chloride, C⁶H⁴.Cl.CH²Cl, with potassium sulphite. See BENZYL-SULPHUROUS ACID (p. 186).

**Nitrotoluenesulphonic Acids, C⁶H⁴(NO²){OH
SO²H}**. (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2], v. 280, 521, 529). When paranitrotoluene (m.p. 54°) is digested for some days with fuming sulphuric acid, and the liquid is diluted with water and saturated with barium carbonate, barium paranitrotoluenesulphonate, [C⁶H⁴(NO²)SO²]²Ba + 3H²O, separates on cooling, in large, shining, yellow, crystalline tufts; by evaporation at ordinary temperatures it is obtained in broad, four-sided tables. The crystals give off all their water over sulphuric acid, and become milk-white when heated (even under water). 100 pts. of water dissolve 3.34 pts. of the salt at 18.6°. The *lead salt*, [C⁶H⁴(NO²)SO²]²Pb + 3H²O, crystallises in shining, pale-yellow tufts, which slowly give off 2 mols. water over sulphuric acid, 3 mols. at a higher temperature. 100 pts. water at 19° dissolve 15.2 pts. of the salt. The acid, treated with hydrogen sulphide in alcoholic solution, is converted into para-amidotoluenesulphonic acid, C⁶H⁴(NH²)SO²H + H²O, which forms long, broad, pale-yellowish, shining prisms giving off their water at 19°.

Orthonitrotoluenesulphonic acid is produced by treating orthonitrotoluene with fuming sulphuric acid (Beilstein a. Kuhlberg); also by the action of fuming sulphuric acid on nitrotolueneparasulphonic acid; it is therefore orthonitrotolueneparasulphonic acid, C⁶H⁴(NO²).(SO²H), (Anna Wolkow). Its *barium salt*, [C⁶H⁴(NO²)SO²]² + 2H²O, forms shining scales or granular crystals much less soluble than the corresponding para-salt, 100 pts. of water at 19° dissolving only 0.57 pt. of it. The *lead salt*, [C⁶H⁴(NO²)SO²]²Pb + 2H²O, forms tufts of dazzling, white, slender needles, which do not give off their water over sulphuric acid; 100 pts. of water at 18° dissolve 0.77 pt. of the salt.

This nitrotoluenesulphonic acid is identical with that which was prepared by Märker, Otto and Beck (*1st Suppl.* 287).

By reduction with ammonium sulphide, it yields ortho-amidotolueneparasulphonic acid, identical with that described by Engelhardt a. Beck (*1st Suppl.* 287, 289).

Orthonitrotolueneparasulphonic chloride, C⁶H⁴(NO²)(SO²Cl), prepared in the usual way, is a heavy oil slowly decomposed by boiling water. The *amide*, C⁶H⁴(NO²)(SO²NH²), obtained by boiling the chloride with ammonium carbonate, and purified by recrystallisation from alcohol, forms shining crystals, and separates from hot water in needles. The *paratoluide*, C⁶H⁴(NO²)(SO²C⁶H⁴(NH²)), is prepared similarly to that from tolueneparasulphonic acid (p. 1168). It is sparingly soluble

in cold, easily soluble in hot water, and separates in shining crystals which melt at 130° – 131° (Wolkow).

Metanitrotoluenesulphonic acid, prepared like its isomerides, forms a barium salt, $[C^6H^4(NO^2)SO^2]^2Ba + 2H^2O$, which crystallises in nodules, and is more soluble than the ortho-salt; 100 pts. of water at 17.5° dissolve 1.145 pt. of it. The lead salt, $[C^6H^4(NO^2)SO^2]^2Pb + 2\frac{1}{2}H^2O$, crystallises in small grains, and easily takes up an additional quantity of lead oxide, forming a basic salt which may be precipitated by alcohol (Beilstein a. Kuhlberg).

Dinitrotoluenesulphonic Acid, $C^6H^3(NO^2)_2SO^2H$, is produced, together with other acids, by treating a solution of toluene in fuming sulphuric acid for a considerable time with very strong nitric acid, at first in the cold, afterwards at a higher temperature. By saturating this mixture with lead oxide and repeated crystallisation, a lead salt was obtained in faintly-yellow shining scales, having the composition $[C^6H^3(NO^2)_2SO^2]^2Pb + 3H^2O$. It gives off $2H^2O$ in a vacuum over sulphuric acid, the remainder when heated. 100 pts. water at 14.5° dissolve 2.64 pts. of this salt (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2], vi. 796).

Nitrobromotoluenesulphonic Acids, $C^6H^3Br(NO^2)SO^2H$. I. *Nitropara-bromotoluene-metasulphonic acid*. The barium salt of this acid is prepared by adding dehydrated and pulverised barium parabromotoluene-metasulphonate (p. 1171) to warm fuming nitric acid, decanting from precipitated barium nitrate, and evaporating. The free acid separated from it by sulphuric acid forms, when concentrated, a faintly yellow syrup which solidifies to a crystalline mass, easily soluble in water, alcohol, and ether, and crystallises by evaporation of its aqueous solution over sulphuric acid in stellate groups of small quickly deliquescent needles.

The acid and its salts have an intensely bitter taste. The salts dissolve easily in water and in alcohol, and crystallise well from water, with the exception of the calcium salt; all however, excepting the sodium salt, in microscopic though very sharply defined crystals.

$C^6H^3(NO^2)BrSO^2K$	Shuttle- or whetstone-shaped crystals.
$C^6H^3(NO^2)BrSO^2Na + 2H^2O$	Tufts of needles an inch long; less soluble than the other salts.
$[C^6H^3(NO^2)BrSO^2]^2Ca$	Small needles.
$[C^6H^3(NO^2)BrSO^2]^2Ba + 2H^2O$	From dilute solutions in hard nodules; from concentrated solution in stellate groups of short flattened needles.
$[C^6H^3(NO^2)BrSO^2]^2Pb + 2H^2O$	Crystallises like the potassium salt.

Microscopical examination of the lead, barium, and potassium salts showed that only one nitro-acid was formed by the process above described (Hübner a. Müller, *Zeitschr. f. Chem.* [2], vii. 14). It does not appear to have been decided whether the nitro-group in this acid occupies the ortho-position (2 or 6) or the meta-position (5).

Nitro-β-metabromotoluenesulphonic acid is easily obtained by nitrating β-metabromotoluenesulphonic acid (p. 1172); only one nitro-acid appears to be thereby produced. The barium salt, $[C^6H^3(NO^2)BrSO^2]^2Ba + 7H^2O$, crystallises in needles more soluble in hot than in cold water. The calcium salt, $[C^6H^3(NO^2)BrSO^2]^2Ca + 9H^2O$, is very soluble in water and in alcohol, and crystallises from alcohol in large prisms. The lead salt, $[C^6H^3Br(NO^2)BrSO^2]^2Pb + 3H^2O$, dissolves easily in water and crystallises in prisms (Wroblevsky, *Zeitschr.* [2], vii. 8).

TOLUIC ACID, $C^6H^5O^2 = C^6H^4(CH^3).COOH$. *Synthesis of Orthotoluic acid*.—Ramsay a. Fittig (*Zeitschr. f. Chem.* [2], vii. 584) have prepared this acid from toluene-orthosulphonic acid (p. 1168), by exchanging the group SO^2H for CN and boiling the resulting nitril with alcoholic potash. By distilling a mixture of the potassium salts of toluene-para-sulphonic acid and toluene-ortho-sulphonic acid with potassium cyanide, and treating the distillate of mixed nitrils with alcoholic potash, ordinary paratoluic acid, mixed with another toluic acid, was obtained. The calcium salts could not be separated by recrystallisation from water, but from 95 p.c. alcohol the isomeric calcium salt crystallised readily, leaving the paratoluic in solution. This isomeric toluate contained $2H^2O$, and gave an acid which crystallised in long shining needles, melting at 102° , and agreed in every respect with orthotoluic acid obtained by oxidation of orthoxylene. The nitro-acid was also prepared, and found to be identical with that obtained from orthotoluic acid.

Metatoluic acid.—This modification is formed when 1 mol. of the calcium salt of urtic acid is intimately mixed with 1 mol. calcium hydrate, and the mixture is heated for several hours in a lead-bath. The toluic acid separated from the product by solution in an acid and distillation with steam, is more soluble than ortho- or paratoluic

acid, and separates in needle-shaped crystals melting at 105° (Fittig, *Deut. Chem. Ges. Ber.* v. 268). By the action of sodium-amalgam on the modification of bromotoluic acid which melts at 205° – 206° (prepared by oxidising bromoxylene, m. p. 205° – 208° , with chromic acid), Ahrens (*Zeitschr. f. Chem.* [2], v. 102) obtained a toluic acid which, when oxidised by chromic acid, gave isophthalic acid, and therefore appeared to be metatoluic acid, but it melted at 90° – 93° , that is to say, from 12° to 15° lower than Fittig's acid. To ascertain the cause of this difference, W. Ramsay prepared the acid according to Ahrens' method, and found that on recrystallising it from alcohol, two very different crystallisations were obtained, viz. druses of dull needles, and transparent crystals, the former consisting of pure paratoluic acid, the latter melting at 105° , just like the metatoluic acid prepared from uvitic acid (*Ann. Ch. Pharm.* clxviii. 263).

Bromotoluic Acid, $C^6H^4Br\begin{Bmatrix} CH^3 \\ COOH \end{Bmatrix}$. F. Landolph, (*Deut. Chem. Ges. Ber.* v.

268) has obtained an acid of this composition by oxidising bromocymene with chromic acid mixture. It is sparingly soluble in cold, more easily in hot water, from which it crystallises in thin needles or laminæ. It dissolves easily also in hot alcohol, in ether, and in chloroform. It is somewhat volatile with vapour of water, melts at 203° – 204° , and sublimes in broad shining needles. Sodium-amalgam easily removes all the bromine, and converts the acid into ordinary paratoluic acid, melting at 176° . Chromic acid mixture decomposes the brominated acid, but partially, even after long boiling, and does not convert it into a bibasic acid. The *calcium salt*, $(C^6H^4BrO^2)^2Ca + 3\frac{1}{2}H^2O$, crystallises from hot water in arborescent needles sparingly soluble in cold water. The *barium salt*, $(C^6H^4BrO^2)^2Ba + 4H^2O$, is similar but less soluble.

This bromotoluic acid dissolves slowly in warm concentrated nitric acid, and the solution diluted with water deposits bromonitrotoluic acid, $C^6H^3(NO^2)Br\begin{Bmatrix} CH^3 \\ COOH \end{Bmatrix}$, which separates from water in needle-shaped crystals. It is soluble in alcohol, ether, and benzene, and does not volatilise with water-vapour. During fusion at about 170° – 180° it decomposes and turns brown. The *barium salt*, which crystallises from hot dilute alcohol in stellate groups of needles, has the composition $(C^6H^3(NO^2)BrO^2)^2Ba + H^2O$.

The bromotoluic acid above described agrees nearly in its properties and those of its salts with that which was obtained by Fittig, Ahrens and Mattheides from coal-tar xylene (*1st Suppl.* 1100). Nevertheless the two can scarcely be identical, since the last-mentioned acid was converted by reduction into isophthalic acid, whereas that prepared from bromocymene was converted by similar treatment into paratoluic acid.

Alpha-toluic or Phenylacetic Acid, $CH^3(C^6H^4).COOH$. This acid, when nitrated, behaves like cinnamic acid (p. 348), forming *para*- and *orthophenylacetic acid*, which latter is converted by oxidation into orthonitrobenzoic acid, shown by the degree of solubility of its barium salt, and by the fact that when reduced by tin and hydrochloric acid, it yields anthranilic acid, which may be converted into salicylic acid (Pirogoff, *Deut. Chem. Ges. Ber.* v. 332).

Toluidine, $C^6H^4N = C^6H^4.NH^2 = C^6H^4(NH^2).CH^3$. Three modifications of this base are known, *para*, *meta*, and *ortho*, formed by reduction of the corresponding nitrotoluenes. Their characteristic properties and reactions have been studied especially by Beilstein and Kuhlberg (*Ann. Ch. Pharm.* clvi. 66; clviii. 341; *Zeitschr. f. Chem.* [2], v. 532; vi. 102, 417; vii. 99; *Jahrb. f. Chem.* 1870, 764; 1871, 712; 1872, 647), and by Wroblevsky (*Zeitschr.* [2], vii. 135, 210, 271, 609; *Jahresb.* 1871, 713; 1872, 649).

Paratoluidine, $C^6H^4(NH^2).CH^3$, is the ordinary solid modification, discovered by Hofmann and Muspratt, and produced by reduction of solid nitrotoluene.

Metatoluidine, $C^6H^3(NH^2).CH^3$, is obtained by the action of tin and hydrochloric acid on the metanitrotoluene discovered by Beilstein and Kuhlberg.

Orthotoluidine, $C^6H^3(NH^2).CH^3$ (Rosenstiehl's *Pseudotoluidine*), is produced from the liquid modification of nitrotoluene, formed, together with solid paranitrotoluene, by direct nitration of toluene (Beilstein and Kuhlberg); apparently also by the following processes:—

a. From *para*-amidotoluic acid, by distillation with soda-lime (Beilstein and Kuhlberg).
 b. By treating monobromotoluene (m. p. 26.4°) with strong, well-cooled-nitric acid, reducing the resulting nitrobromotoluene with tin and hydrochloric acid, and debrominating the bromotoluidine with sodium-amalgam (Körner, *Compt. rend.* lxviii. 824; *Jahresb.* 1869, 677).

γ. By a similar series of processes from the mixture of *para*- and *orthobromotoluene* produced by the direct action of bromine on toluene (p. 1164) (Hübner and Wallach,

Zeitschr. f. Chem. ii. 530; *Jahresb.* 1869, 678. See further, Rosenstiehl, *Compt. rend.* lxi. 53, 469; *Jahresb.* 1869, 679, 680).

The following table exhibits the most characteristic differences between the three isomeric toluidines and their derivatives:

Isomeric Toluidines.

	Para	Meta	Ortho
Toluidine {b.p.	198°	197°	197°
{sp. gr.	—	0.998 at 25°	0.998 at 25.5°

Colour produced by toluidine with sulphuric and nitric acid . . .	blue	none	none

Bromotoluidines. Wroblevsky a. Kurbatow (*Zeitschr. f. Chem.* [2], vi. 165) have obtained two bromotoluidines, α and β , by reduction of the two nitrobromotoluenes formed by nitration of solid bromotoluene (p. 1167). *α -Bromotoluidine* is a liquid which solidifies at -2° . Its nitrate forms macroscopic crystals, of which 1,000 pts. of water at 11.5° dissolve 8.27 pts. *β -Bromotoluidine* forms prismatic crystals melting at 67° . Its nitrate also crystallises in prismatic forms; 1,000 pts. of water at 11.5° dissolve 4.6 pts. of it. Heynemann (*Zeitschr.* [2], vi. 402) has obtained a base which he designates as *parabromometatoluidine*, by reduction of the corresponding bromonitrotoluene; it melts at 80° , but does not easily resolidify. 9 pts. of the nitrate dissolve in 1,000 pts. water at 17° .

Metabromotoluidine. $C_6H_4Br.NH_2$, either $C_6OH^3.NH^2.Br.H.H.H$ (1:2:3) or $C_6CH^3.NH^2.H.H.Br.H$ (1:2:5). Wroblevsky (*Zeitschr.* vii. 146) prepares this compound as follows. Crude toluidine is mixed with rather more than the theoretical quantity of glacial acetic acid, and boiled for 16 hours in a flask with upright tube, to separate the para- and ortho-modifications; the uncombined toluidine is separated from the solidified (the greater) portion by distillation, and this toluidine is heated for three days with the required quantity of glacial acetic acid. *Acetone*

toluide is thus obtained as a solid body which, however, melts not at 105° , but at 98° . By suspending it in water and dropping bromine into the liquid, bromacetoluide, $C^6H^4Br(NH.C^2H^3O)$, is produced, which, when purified, crystallises in long shining needles melting at 156° – 157° , and dissolving easily in alcohol and in boiling water. This acetyl-compound, decomposed by alcoholic potash, yields metabromorthotoluidine, which, after distillation with steam, is solid, and crystallises in fine large octohedrons. It melts at 57° , and boils, with complete decomposition, at about 240° ; it dissolves easily in alcohol, very sparingly in water. Its hydrochloride, nitrate, and sulphate, $(C^6H^4BrNH^2)SO^4 + 1\frac{1}{2}H^2O$, are all soluble in water and crystallise well. The nitrate, decomposed with nitrous acid and alcohol, yields metabromotoluene, which boils at 182° , and is oxidised by chromic acid solution to meta- (ordinary) bromobenzoic acid, melting at 153° . The perbromide, $C^6H^4Br.NH^2.Br^2$, decomposed with absolute alcohol, yields orthometadi-bromotoluene, $C^6H^4Br^2$ (1 : 2 : 3) or (1 : 2 : 5).

Orthobromometatoluidine, $C^6H^4Br.(NH^2)_{\infty}$ (1 : 2 : 3 or 1 : 2 : 5), is obtained by the action of potash on orthobromometacetoluide, which is formed by treating metacetoluide with bromine. It is a liquid boiling at 240° , and smelling very much like ordinary toluidine. Its *nitrate* crystallises in small, reddish, sparingly soluble prisms. When it is converted into the diazo-compound, and the corresponding perbromide is decomposed by absolute alcohol, dibromotoluene, $C^6H^4Br_2$, is formed as a solid melting at 42.5° and boiling at 249° (Wroblevsky, *Zeitschr.* [2], vii. 609).

Dibromotoluidines.—1. *Dibromorthotoluidine*, $C^6H^4Br^2(NH^2)_{\infty}$, is produced by passing bromine (4 at.) into an aqueous solution of the hydrochloride of orthotoluidine. The base separated by lime crystallises in beautiful nacreous needles easily soluble in alcohol, nearly insoluble in water, melting at 50° . It does not combine with acids (Wroblevsky, *Zeitschr. f. Chem.* [2], vii. 210).

2. Acetometatoluide, treated with bromine in presence of water, yields dibrom-acetometatoluide, $C^6H^4Br^2.NH.C^2H^3O$, which forms flat needles melting at 164° , and converted, by decomposition with alkali, into dibromometatoluidine, $C^6H^4Br^2.(NH^2)_{\infty}$. This compound crystallises in silky needles melting at 92.5° ; does not unite with acids. By removing the amidogen groups from this dibromotoluidine, a dibromotoluene, $C^6H^4Br^2$, is obtained having the constitution 1 : 3 : 5 (see table, p. 1176).

3. The dibromotoluidine obtained by reduction of the nitro-dibromotoluene produced by nitration of para-orthodibromotoluene (p. 1165), crystallises in nacreous scales melting at 95° , and does not combine with acids (Wroblevsky, *Zeitschr.* [2], vi. 239).

4. The dibromotoluidine obtained from the nitrodibromotoluene formed by nitration of ortho-metadibromotoluene, forms silky prismatic crystals melting at 83° (Wroblevsky, *loc. cit.*)

Tribromotoluidine, $C^6H^4Br^3.NH^2$, is formed by passing bromine-vapour (4 at.) into the hydrochloric acid solution of metatoluidine, and separates in white flocks which may be purified by distillation with vapour of water. It dissolves sparingly in alcohol, and crystallises therefrom in long needles melting at 97° . It does not unite with acids. On adding it to alcohol saturated with nitrous acid, a violent action takes place, resulting in the formation of tribromotoluene, $C^6H^4Br^3$. Metatoluidine differs therefore from para- and orthotoluidine in yielding, by bromination, a tribrominated instead of a dibrominated product (Wroblevsky, *loc. cit.*)

Chlorotoluidines. Orthonitrotoluene, reduced with tin and hydrochloric acid, yields a chlorotoluidine, $C^6H^4Cl(NH^2)$, which melts at 29.5° , boils at 241° , dissolves easily in alcohol, ether, and carbon sulphide. Its *hydrochloride* forms thin white crystals. The *nitrate* forms large thin quadrangular striated crystals, of which 100 pts. water at 19° dissolve 3.712 pts. By conversion into the diazo-compound, and decomposition of this compound with hydriodic acid, a chloriodotoluene is obtained boiling at 240° (Beilstein a. Kühlberg, *Zeitschr. f. Chem.* vi. 102).

Dichlorotoluidine, $C^6H^4Cl^2.NH^2$.—The nitrodichlorotoluene produced by nitration of the dichlorotoluene, which boils at 195° – 200° , yields, by reduction, a dichlorotoluidine which forms dazzling white, elongated laminae, melts at 88° , and boils at 250° (Wroblevsky a. Pirogow, *Zeitschr.* [2], vi. 164).

Iodotoluidine. *Para-iodorthotoluidine*, $C^6H^4I.(NH^2).CH^3$, prepared by reduction of para-iodorthonitrotoluene (p. 1167), forms needle-shaped colourless crystals which melt at 48° – 49° , and boil, with rapid decomposition, at 273° . It dissolves very easily in alcohol, ether, and carbon sulphide. The *nitrate* crystallises from hot water in colourless nacreous laminae. 1000 pts. of water at 16° dissolve 9.5 pts. of this salt. The *diazo-compound*, which is formed from it with difficulty, is decomposed by water, even at ordinary temperatures, yielding dinitro-iodocresol, $C^6H^3(HO)(NO^2)_2.CH^3$,

which separates in slender yellow needles melting at 75°, and exploding at a higher temperature. Caustic soda dissolves this dinitrocresol, and hydrochloric acid precipitates it from the solution without alteration (Heynemann, *Zeitschr.* [2], vi. 402).

Nitrotoluidines and Nitro-acetoluides. *Dinitropara-acetoluide*, $C^6H^4(NO^2)_2(NH.C^2H^3O)_n$, is obtained by adding para-acetoluide (1 pt.) in small portions to well-cooled nitric acid (4 pts.) of 49° B.; the product is precipitated with snow, washed with water, then, after drying, with ether, and recrystallised from alcohol. It forms long, pale yellow needles, much more soluble in hot than in cold alcohol, melting at 190-5°.

Dinitroparatoluidine, $C^6H^4(NO^2)_2(NH^2)_n$, is easily obtained by boiling the acetyl-derivative with alcoholic potash; it is precipitated by water, recrystallised from benzene, and finally from boiling carbon sulphide. It crystallises in yellow needles, melts at 168°, and may be sublimed in small quantities without decomposition. It is but slightly soluble in alcohol even at the boiling heat, more soluble in benzene, especially when boiling, nearly insoluble in ether; 1000 pts. of carbon sulphide at 13° dissolve 3.2 pts. of it. It is but slowly reduced by tin and hydrochloric acid, the product being apparently, not a triamine base, but a tolyleno-diamino. Dinitrotoluidine suspended in alcohol or in strong nitric acid is not acted on by nitrous acid at ordinary temperatures, but at boiling heat the dinitrotoluidine dissolves, being probably converted into dinitrotoluene (Beilstein a. Kuhlberg, *Ann. Ch. Pharm.* clviii. 341).

Metanitro-orthacetoluide, $C^6H^4(NO^2)_n(NH.C^2H^3O)_n$, or $C^6H^3(NH.C^2H^3O)(NO^2)HHH$, is formed by adding orthacetoluide in small portions to well-cooled nitric acid of 45° B. The product is precipitated with snow, washed with water, and recrystallised from alcohol. It is very slightly soluble in water even at the boiling heat, and crystallises therefrom in microscopic needles melting at 196°-197°. From alcohol, in which it is more soluble, it crystallises in small lemon-yellow needles.

Metanitro-orthotoluidine, $C^6H^3(NO^2)_n(NH^2)_n.CH^3$, is obtained by heating the acetyl-derivative with a mixture of 1 vol. sulphuric acid and 3 vols. water, and precipitating with ammonia; also by boiling the acetyl-derivative with alcoholic potash. It may be purified by recrystallisation from water or from aqueous alcohol. It is very slightly soluble in boiling water, and crystallises therefrom in small lemon-yellow needles which, after drying, form a felted mass; it is easily soluble in alcohol. From its hot solution in dilute nitric acid, the free base crystallises in long, flat, yellow, shining needles melting at 127°-128°. By nitrous acid and alcohol it is converted into metanitrotoluene (Beilstein a. Kuhlberg, *loc. cit.*)

Orthonitrometacetoluide, $C^6H^4(NO^2)_n(NH.C^2H^3O)_n.CH^3$, prepared by treating acetometatoluide with cooled nitric acid of 46.5° B., precipitating with snow, and recrystallising several times from water, forms small cubes, or when crystallised by slow evaporation, larger rhombic crystals. It dissolves easily in boiling alcohol, very sparingly in water even at the boiling heat. Melts at 101°-102°.

Orthonitrometatoluidine, $C^6H^4(NO^2)_n(NH^2)_n.CH^3$, is formed by treating the acetyl-compound just described with the theoretical quantity of alcoholic potash. It melts at 133°-134°. By converting this base into diazotoluene by Griess's reaction, and decomposing the sulphate of this diazotoluene with absolute alcohol, a nitrotoluene is obtained, which boils constantly at the temperature of *orthonitrotoluene* and remains liquid at -20°. Hence, it may be inferred that the nitro group in the base and its acetyl-derivative under consideration occupies the ortho-position (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2], vii. 99).

Furfurotoluidine, $C^6H^4O^2N^2$. Toluidine in alcoholic solution acts but slowly on furfural; a more decided action is obtained with toluidine salts. A hot mixture of 12 pts. toluidine hydrochloride and 9 pts. toluidine dissolved in 160 pts. alcohol with 8 pts. furfural, also dissolved in 150 pts. alcohol, solidifies on cooling to small red, needle-shaped crystals of *furfurotoluidine hydrochloride*, $C^6H^4O^2N^2.HCl$. The *nitrate*, $C^6H^4O^2N^2.NO^3H$, prepared in like manner with a mixture of 14 pts. toluidine nitrate and 9 pts. toluidine dissolved in 100 pts. alcohol with 8 pts. furfural in 100 pts. alcohol, forms purple needles. *Furfurotoluidine*, prepared by triturating ether of its salts with ammonia and kneading the resulting mass with water, forms, when purified by solution in ether, a brown, amorphous, brittle mass (Stenhouse, *Ann. Ch. Pharm.* clvi. 197).

Appendix to Furfurotoluidine. **FURFURANILINE**, $C^6H^4O^2N^2$. This base, prepared in a similar manner, forms a hydrochloride which crystallises in small purple needles, insoluble in benzene, carbon sulphide, and water, quickly decomposed by boiling with dilute acids or alkalis. The *nitrate* forms similar but larger crystals. The free base

is a brown mass, the alcoholic solution of which decomposes quickly in contact with the air or on boiling, and then no longer forms crystallisable salts (Stenhouse).

TOLUIDINES, DIMETHYLISED. On the formation of these bases by the action of heat on trimethyl-phenylammonium iodide, see AMINES (p. 57).

TOLUIDINE-SULPHONIC ACIDS. II. L. Buff (*Deut. Chem. Ges. Ber.* iii. 796) has examined these acids with results nearly the same as those obtained by Malyschew (*1st Suppl.* 288). He finds that the β -acid, heated with potassium hydrate, yields an oily base which does not form crystallisable salts; probably oxytoluidine, $C^6H^3(OH)(NH^2).CH^3$.

TOLUENE, C^6H^{12} . Syn. with STILBENE (p. 1099).

TOLUENE ALCOHOL, HYDRATE, and OXIDE. See HYDROBENZOÏN and DROXYBENZOÏN, under BENZOÏN (pp. 171-176).

TOLYL (DI-), C^6H^{14} = $C^6H^4\{CH^3\}_2$. This hydrocarbon, isomeric with dibenzyl and benzyl-toluene (p. 183), is produced by the action of sodium on parabromotoluene (p. 1161).

Sodium acts very briskly on a solution of solid bromotoluene in anhydrous ether, and if the liquid is not well cooled, hydrogen is evolved and a large quantity of toluene is regenerated, the formation of which indeed cannot be completely evaded, even if the vessel is surrounded by a freezing mixture. The other products of the reaction are a large quantity of a yellow solid (not further studied), which is sparingly soluble in alcohol, and can thus be easily separated from two isomeric ditolyls which dissolve readily in alcohol. That which is present in the largest quantity is a solid, which crystallises from ether in splendid monoclinic prisms and from alcohol in white plates melting at 121° . The second ditolyl is a liquid, having an aromatic smell and boiling at 283° - 288° .

By acting with sodium on crude bromo- and chlorotoluene, only a small quantity of the solid ditolyl is obtained; the chief product is a liquid, which appears to be identical with the ditolyl (b. p. 272°) which Fittig obtained (*Ann. Ch. Pharm.* cxxxix. 178) by the action of sodium on bromotoluene. That prepared from chlorotoluene boiled at 273° - 278° (Zincke, *Deut. Chem. Ges. Ber.* iv. 396).

TOLYL ISOCYANATE, $N(CO)C^6H^7$. Colourless liquid boiling at 185° . See CYANIC ETHERS (p. 407).

TOLYLAMINES. *Azoditolyldiamine, $C^6H^{13}N^2$.* — Hofmann a. Geyger (*Deut. Chem. Ges. Ber.* v. 476), in attempting to prepare this base by heating toluidine to fusion on a saturated solution of common salt, and passing a rapid stream of nitrous acid through it, obtained the isomeric compound diazamidotoluene; which crystallises in lemon-yellow needles; and decomposes on boiling with hydrochloric acid into nitrogen, cresol, and toluidine:

Trichlorethylidene-ditolyldiamine, $C^6H^{11}Cl^3N^2$ = $CCl^3.CH(NHC^6H^7)^2$ (Wailach, *Deut. Chem. Ges. Ber.* v. 252).—A base produced by the action of chloral on toluidine:

The reaction is attended with rise of temperature, and the mass, which solidifies on cooling, crystallises from ether in transparent prisms which melt at 114° - 115° , but are decomposed by continued heating to 100° . It cannot be distilled.

Trichlorethylidene-oxethyltolylamine, $CCl^3-CH \begin{Bmatrix} OC^2H^5 \\ NH(C^6H^4-CH^3) \end{Bmatrix}$. If in the preparation of the preceding compound a little alcohol be added to the product while still warm, this oxethyl-compound is obtained, chiefly from the mother-liquor, in large tabular crystals very easily soluble in alcohol and ether. It crystallises with great facility, especially from ether mixed with a little alcohol, which deposits it in hard thick crystals an inch in length. It melts at 76° - 77° , and solidifies with difficulty after fusion; cannot be distilled without decomposition. It is insoluble in water, and is gradually decomposed by boiling with it, emitting an unpleasant odour. Towards aqueous alkalis it is moderately stable at ordinary temperatures. Aqueous acids separate toluidine salt from it.

Toluidine fused with *chloral alcoholate* forms trichlorethylidene-ditolyldiamine,

which, when boiled with alcohol, appears to be converted into trichlorethylidene-oxethyltolylamine (Wallach).

TOLYL CARBAMIC ETHERS or **TOLYLURETHANES**. *Ethyltolylcarbamate*, $\text{CO} \begin{Bmatrix} \text{NH}(\text{C}^2\text{H}^5) \\ \text{OC}^2\text{H}_5 \end{Bmatrix}$, is obtained by the action of chlorocarbonic ether on toluidine in presence of ether. It crystallises with difficulty from the crude product in long prisms insoluble in water, easily soluble in alcohol and ether, melting at 52° . By distillation with phosphoric anhydride it yields tolyl isocyanate (Hofmann, *Proc. Roy. Soc.* xix. 108).

Butyltolylcarbamate, $\text{CO} \begin{Bmatrix} \text{NH}(\text{C}^4\text{H}_9) \\ \text{OC}^4\text{H}_9 \end{Bmatrix}$, is obtained by the action of butyl chlorocarbonate on liquid toluidine (b. p. 198°). It is liquid, does not solidify at -10° , and boils with partial decomposition at 275° – 280° .

TOLYLENEDIAMINES, $\text{C}^6\text{H}^4(\text{NH}_2)^2$ (Beilstein u. Kuhlberg, *Ann. Ch. Pharm.* clviii. 335; *Zeitschr. f. Chem.* [2], vii. 134). Three of these isomeric bases have been obtained, viz:

	1	2	3	4	5	6
1. Paraorthotolylene-diamine	$\text{C}^6\text{H}^4\text{NH}_2$	H	NH_2	H	H	H
2. Parametotolylene-diamine	C^6H^4	H	NH_2	NH_2	H	H
3. Metaorthotolylene-diamine	C^6H^4	NH_2	NH_2	H	H	H

1. *Paraortho*, $\text{C}^6\text{H}^4(\text{NH}_2)^2$ — CH_3 .—This is the known form obtained by reduction of dinitrotoluene. Hofmann gives 99° as its melting point, and about 280° as the boiling point. The *sulphate*, $\text{C}^6\text{H}^4(\text{NH}_2)^2\text{H}^2\text{SO}_4 + 2\text{aq.}$, crystallises from water in long, prismatic, glistening crystals, which do not lose their water of crystallisation over sulphuric acid; 100 pts. of water at 19.5° dissolve 5.58 pts. of salt.

2. *Parametotolylene-diamine*, $\text{C}^6\text{H}^4(\text{NH}_2)^2$ — CH_3 .—This modification is obtained by reduction of nitroparatoluidine with tin and hydrochloric acid. The solution is freed from tin by hydrogen sulphide, and evaporated to dryness; the residue, intimately mixed with pulverised caustic lime, is then distilled from a combustion-tube. It is obtained in brilliant white scales, which melt at 88.5° , and distil unchanged at 265° . It is moderately soluble in cold, more soluble in hot water. The aqueous solution of the base is extremely unstable, becoming black on standing for a few hours. The hydrochloride crystallises in long needles, extremely soluble in water. The *sulphate*, $\text{C}^6\text{H}^4(\text{NH}_2)^2\text{H}^2\text{SO}_4 + 1\frac{1}{2}\text{H}_2\text{O}$, forms magnificent, white, glistening scales; 100 pts. of water at 19.5° dissolve 9.29 pts. of salt. Both the free base and its salts become oxidised when exposed to the air, much more readily than paraorthotolylene-diamine and its salts.

3. *Metaorthotolylene-diamine*, $\text{C}^6\text{H}^4(\text{NH}_2)^2$ — CH_3 . Nitro-orthotoluidine is attacked with great energy by tin and hydrochloric acid. The free base is colourless and crystalline; it melts at 80° , and boils constantly and unchanged at 270° . It is even less stable when exposed to the air than parametotolylene-diamine. The *sulphate*, $\text{C}^6\text{H}^4(\text{NH}_2)^2\text{H}^2\text{SO}_4$, is anhydrous and pulverulent, difficultly soluble in cold, more so in hot water. 100 pts. of water at 11.5° dissolve .84 pt. of the salt.

The following is a tabular arrangement of the characteristics of the isomeric tolylenediamines:

	Paraortho	Parameta	Metaortho
Melting point . . .	90°	88.5°	80°
Boiling point . . .	280°	265°	270°
The forms . . .	long prisms	scales	powder
H^2SO_4 contains . . .	$2\text{H}_2\text{O}$	$1\frac{1}{2}\text{H}_2\text{O}$	—
salt } 100 pts. H_2O } dissolve }	5.58 pts. at 19.5°	9.29 pts. at 19.5°	0.84 pt. at 11.5°

TOLYLURETHANES. See TOLYL CARBAMIC ETHERS.

TOLYLXYLIDINE. See XYLIDINE.

TOPAZ. On the crystalline form of this mineral, see P. Groth (*Jahrb. f. Mineralogie*, 1870, 624; *Jahresb. f. Chem.* 1870, 1310). On its Pyroelectric properties, W. Hankel (*Jahrb. f. Mineralogie*, 1871, 287; *Chem. Soc. J.* [2], ix. 869). On the crystallographic and chemical relations of Topaz, Andalusite, and Staurolite, O. Rammeisberg (*Zeitschr. Geol. Ges.* xlv. 87).

TOURMALINE. A very fine black tourmaline from the granite of Giglio was found to have a specific gravity 3.15 and the following composition:

SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	Na ² O	K ² O	B ² O ³	F
36.71	31.57	9.30	8.51	0.64	0.40	2.83	0.70	5.56	1.85 = 98.16.

This tourmaline is remarkable for its large percentage of ferrous oxide (E. Bechi, *Jahrb. f. Mineralogie*, 1872, 95).

TRACHYTE. For analyses of the trachytes of Lake Lanch, see L. Drossel (*Jahrb. f. Mineralogie*, 1870, 559; *Jahresb. f. Chem.* 1870, 1360); of the trachytes of Auvergne, see A. v. Lasaulx (*Jahrb. f. Mineralogie*, 1871, 673; 1872, 171, 281, 337; *Jahresb. f. Chem.* 1871, 1210; 1872, 1163).

TRANSPIRATION OF LIQUIDS. See LIQUIDS (p. 756).

TRAP. Vanadium and titanium have been found by Engelbach in the trap-rocks of the Rhine district, and by R. Apjohn in those of the Giant's Causeway, and in one from the Vicentine territory in Italy (*Chem. News*, xxvi. 183; *Chem. Soc. J.* [2], x. 1116).

TRIACETAMIDE, $N(COCH^3)^2$. See ACETAMIDE (p. 3).

TRIACETYL-DERIVATIVES OF CARBO-HYDRATES. See CELLULOSE (1st Suppl. 418); and the articles GLYCOGEN, INULIN, STARCH, and SUGAR, in this volume.

TRIAMINES, CHROMIC. See CHROMIUM (p. 336).

TRIAMYLMELAMINE, $C^3H^4(C^2H^4)^3N^4$, is formed, like triethylmelamine (1st Suppl. 808), by desulphuration of amyl-sulphocarbamide. It is a strongly alkaline syrup, insoluble in water and in hydrochloric acid. The *platinochloride*, $C^3H^4(C^2H^4)^3N^4 \cdot 2HCl \cdot PtCl_4$, forms a network of yellow crystals soluble in water, slightly soluble in alcohol. By boiling with hydrochloric acid it is decomposed, with evolution of ammonia (Hofmann, *Deut. Chem. Ges. Ber.* iii. 264).

TRIBENZHYDROXYLAMINE, $N(C^6H^5O)^3$. See p. 155.

TRIBENZYLAMINE. See BENZYLAMINE (p. 182).

TRIBROMHYDRIN. See BROMHYDRINS (p. 209).

TRIBROMO-DIOXYBENZOIC ACID, $C^6H^2Br^3O^4$. See DIOXYBENZOIC ACID (p. 433).

TRIBROMO-RESORQUINONE, $C^6HBr^3O^2$. See RESORCIN (p. 1042).

TRIBUTYLAMINE. See BUTYLAMINES (p. 222).

TRICHLORACETAMIDE.

TRICHLORACETIC ACID.

TRICHLORACETOLUIDE.

} See ACETIC ACID (pp. 9, 10).

TRICHLORACETOLACTIC ACID, $CCl^3-CH=CH-CH \begin{Bmatrix} OH \\ CO^2H \end{Bmatrix}$. An acid produced by the prolonged action of strong hydrochloric acid on the corresponding cyanhydrin formed by the action of hydrocyanic acid on crotonic chloral. It melts at 40° (p. 400).

TRICHLORETHYL OXIDE, $C^2H^2Cl^3O$. See ETHYL OXIDE (p. 484).

TRICHLORETHYLENE-DITOLYLAMINE, $CCl^3-CH[NH(C^7H^7)]^2$. See TOLYLAMINES (p. 1179).

TRICHLORHYDRIN. See CHLORHYDRINS (p. 319).

TRICHLOROCROTONAMIDE.

TRICHLOROCROTONIC ACID.

} See CROTONIC ACID (pp. 397, 398).

TRICHLOROFORMENE-SULPHOCHLORIDE. On the reaction of this compound with potassium sulphite, see SULPHITES (p. 1136).

TRICHLORO-DIBROMONITROETHANE, $C^2Cl^2Br^2(NO^2)^2$, and **TRICHLOROTRINITROETHANE**, $C^2Cl^3(NO^2)^3$. See CARBON CHLORIDES (p. 259).

TRICODRINE, $C^{12}H^{12}N^4O^4$. See CODRINE (pp. 373-375).

TRIDYMITE. This variety of crystallised silica (1st Suppl. 1110) occurs but rarely in the older rocks, or in the newer rocks of a comparatively basic character; it is found chiefly in trachytes, associated with sanidin and acid plagioclases. It often occurs with hornblende, rarely with augite, never (like quartz) with olivin (F. Zirkol, *Pogg. Ann.* cxl. 492).

A. Streng has found tridymite in the porphyrites of Waldböckelheim, in very numerous small crystals, exhibiting the forms ∞P and oP , as well as the characteristic twin formations, and sometimes covered with octohedrons of magnetic oxide. With regard to this first observed occurrence of tridymite in the older rocks, Streng observes that the rock in which it occurs is not very acid, also that the amount of silica in the volcanic rocks which contain tridymite does not exceed 69 p. c. (*Jahrb. f. Min.* 1871, 933; 1872, 265; *Chem. Soc. J.* [2], ix, 128).

Tridymite has been found by Sandberger in small druses of a coarse-grained dolerite of the Frauenberg, near Heubach; by H. Wolf in the trachyte from the neighbourhood of Quito; by G. vom Rath very abundantly in the porous scoriceous trachytes of the Stenzelberg in the Siebengebirge, also in outcasts from Vesuvius in the eruption of 1822; by K. Hofmann in the pores of the augitic andesites of the Guttin and Royals ranges (*Jahresb. f. Chem.* 1872, 1098).

TRIEPIO ACID. An acid said by Maumené (*Compt. rend.* lxxv, 85) to be formed by the action of potassium permanganate on cane-sugar.

TRIETHIDE, STANNIC. See STANNETHYLS and TIN (p. 1159).

TRIETHYLARSINE. See ARSINES (p. 107).

TRIETHYL-CARBINOL, $C^3H^{10}O = (C^2H^5)^3.COH$. This tertiary heptyl alcohol is formed by the action of zinc-ethyl (2 mols.) on propionyl chloride (1 mol.) The mixture after a few hours forms a thick mass, and on decomposing this mass with water and distilling, the alcohol passes over, together with an oily body which remains undissolved when the whole is treated with a large quantity of water. The alcohol is separated from the aqueous solution by means of potassium carbonate, then dried with baryta and rectified.

Triethyl-carbinol is a colourless liquid having a sp. gr. of 0.8593 at 0° , becoming viscid at -20° , and boiling at 140° – 142° . It has a camphorous odour, and an aromatic taste, burning at first, but afterwards cooling. By oxidation with chromic acid mixture it yields a hydrocarbon which unites with bromine, and probably consists of heptylene, $C^7H^{14} = C \left\{ \begin{smallmatrix} (C^2H^5)^2 \\ CH.CH^2 \end{smallmatrix} \right.$. Acetic acid was also formed, together with a more highly carbonated acid (propionic acid). Diethylketone does not appear to be formed (Nabapetian, *Zeitschr. f. Chem.* [2], vii, 274).

TRIETHYL-METHANE, $CH(C^2H^5)^3$. A modification of heptane, produced by the action of zinc-ethyl and sodium on orthoformic ether. The crude product is fractionated, the portion distilling at about 100° is agitated with sulphuric acid, and the undissolved portion is washed, dried, and rectified. Triethylmethane thus obtained is a colourless liquid having a faint odour of petroleum, a sp. gr. of 0.689 at 27° , and boiling at 96° . Vapour-density = 101.5° (Ladenburg, *Deut. Chem. Ges. Ber.* v, 762).

TRIETHYL-PHOSPHINE OXIDE. See PHOSPHINES (p. 953).

TRIETHYL-PYROPHOSPHOSULPHOBROMIDE, $P^2S^3(OC^2H^5)^3Br$. See SULPHOPHOSPHORIC ETHERS (p. 1123).

TRIETHYL-SILICOL. See SILICIC ETHERS (p. 1083).

TRIETHYLSULPHINE PERIODIDE. See IODIDES (p. 678).

TRIGENIC ACID. The trigenic acid of the allyl series, $C^3H^5N^3O^3$, is formed by the action of cyanic acid on acrolein (p. 26).

TRIGLYCOLLAMIC ACID. On the constitution of this acid, see Heints (*J. pr. Chem.* [2], iii, 69, 120; *Chem. Soc. J.* [2], ix, 236) and Claus (*J. pr. Chem.* [2], iii, 123).

TRIMETHACETIC ACID, $C^3H^5O^3 = C(CH^3)^3.CO^2H$ (Butlerow, *Deut. Chem. Ges. Ber.* v, 478). This acid is best prepared by acting on tertiary butyl iodide, $C(CH^3)^3I$, with mercuric cyanide, whereby tertiary butyl cyanide is produced:

digesting this cyanide with alcoholic potash, and decomposing the resulting potassium salt with sulphuric acid. By dehydrating the distillate with phosphoric anhydride, trimethacetic acid is obtained as a vitreous mass intersected by crystals. It melts at 34° – 36° , and boils at 161° ; is not deliquescent, but dissolves slowly in water. The barium salt, $(C^3H^5O^2)^2Ba + 5H^2O$, is easily soluble, and crystallises in stellate needles. The silver salt, $C^3H^5O^2Ag$, crystallises from aqueous solution in laminae, from an acid solution in small needles, a reaction by which it is distinguished from the silver salt of ordinary valeric acid.

TRIMETHYL-CARBINOL, $C(CH_3)_3.CO.H$. See BUTYL ALCOHOLS (p. 219).

TRIMETHYLENE GLYCOL and **ETHERS**. The bromide, $C_3H_6Br_2$, is formed by the action of hydrobromic acid on allyl bromide (p. 40). See PROPYLENE-COMPOUNDS (pp. 1017, 1020).

TRIMETHYL-ETHYL-METHANE, $C_8H_{18} = C \begin{Bmatrix} (CH_3)_3 \\ C_2H_5 \end{Bmatrix}$. This form of hexane, produced by the action of zinc-ethyl on tertiary butyl iodide, is a colourless liquid boiling between 43° and 48° , and having a vapour-density = 2.917.

TRIMETHYL-PHENYLAMMONIUM IODIDE, $(CH_3)_3(C^6H_5)N.I$. On the formation of dimethyltoluidines by the action of heat on this compound, see AMINES (p. 57).

TRIMETHYL-TOLYLAMMONIUM IODIDE, $(CH_3)_3(C^6H_4)N.I$ (p. 58).

TRINITRO-AZOBENZENE. When crystals of azobenzene are dissolved in nitric acid of sp. gr. 1.5, and the solution is boiled, sulphur-yellow crystals of trinitro-azobenzene, $C_6H_3(NO_2)_3.NO$, gradually separate out, and afterwards needles of trinitro-azobenzene, $C_6H_3(NO_2)_3.N$, which melt at 112° (Petrie, *Zeitschr. f. Chem.* [2], vi. 564).

TRINITRO-CRESOTIC ACID, $C_8H_3(NO_2)_3O_2$. This is the composition of *nitrococcus acid*, the product of the action of nitric acid on carminic acid. See COCHINEAL (p. 367).

TRINKERITE. A fossil resin occurring in the Eocene lignite of Carpano, near Albano in Istria, in thick transparent and translucent masses, having a fatty lustre and hyacinth-red to chestnut-brown colour. It has a flat conchoidal fracture, and is often traversed by parallel clefts. Hardness = 1.5 to 2; sp. gr. = 1.025. Becomes strongly electric when rubbed. Melting point 168° – 180° . When heated it gives off pungent vapours rich in hydrogen sulphide. It is insoluble in water, sparingly soluble in ether and in alcohol, perfectly soluble in hot benzene. An analysis by H. Hlasiwetz gave, without any ash, the numbers *a* (Tschermak, *J. pr. Chem.* [2], ii. 258).

Trinkerite has also been found by Niedzwiedzki (*Jahrb. f. Mineralogie*, 1871, 641) in flat lumps imbedded in a carbonaceous marl at Gams, near Hiefau in Styria. An analysis, also by Hlasiwetz, gave the numbers *b*.

	O	H	O	S
<i>a.</i>	81.1	11.2	3.0	4.7 = 100
<i>b.</i>	81.0	10.0	3.1	4.1 = 100

The composition does not differ much from that of Tasmanite (v. 698) (Tschermak, *J. pr. Chem.* [2], ii. 258).

A resin, intermediate between retinite and trinkerite, occurring in the lignite of Agka, in the Bakonyer forest, Veszprémer Comitat, Hungary, consists, according to Hlasiwetz, of 81.69 C., 10.20 H., 1.87 S., and 6.34 O. (= 100).

TRIOXYADIPIC ACID, $C_8H_4O_7$. See ADIPIC ACID (p. 29).

TRIOXYTERMIC, TRIOXYCHLORIC, and TRIOXYIODIC ACIDS. These names are given by Kämmerer to BROMIC, CHLORIC, and IODIC ACIDS (p. 592).

TRIOXYNAPHTHALENE, $C_{10}H_4O_3$. See NAPHTHOLS (pp. 841, 842).

TRIOXYNAPHTHAQUINONE, $C_{10}H_2O_3$. See NAPHTHAQUINONE (p. 837).

TRIPHENYLAMINE, $N(C^6H_5)_3$. See PHENYLAMINES (p. 945).

TRIPHENYL-BIURET, $C_{18}H_{15}N_3O_2$. See BIURET (p. 193).

TRIPHENYL-METHANE, $CH(C^6H_5)_3$. See PHENYLMETHANES (p. 948).

TRIPHENYLBISANILINE-SULPHONIC ACID. See ANILINE (p. 77).

TRISALICENO-SALICENIN, $C_{15}H_{10}O_8 = 4C^6H_3O_2 - 3H_2O$. See SALICENIN (p. 857).

TRISALICYLO-SALICYLIC ACID. See SALICYLIC ANHYDRIDES (p. 1067).

TRITHIONIC ACID. See SULPHUR, OXYGEN ACIDS OF (p. 1141).

TRITICUM. On the constituents of the rhizomes of *Triticum repens*, see Ludwig a. Müller (*Arch. Pharm.* [2], cl. 132; *Chem. Soc. J.* [2], x. 840).

TRÖGGERITE. See URANIO ARSENATES (p. 1190).

TRONA. O. Popp (*Ann. Ch. Pharm.* clv. 348) has analysed three sorts of Egyptian Trona: *a*, small transparent prismatic crystals, having nearly the com-

position, $2\text{Na}^+\text{O}\cdot 3\text{CO}^+ + 4\text{H}^+\text{O}$; b and c very impure saline masses, with few or no distinct crystals:

$2\text{Na}^+\text{O}\cdot 3\text{CO}^+$	$\text{Na}^+\text{O}\cdot \text{SO}^+$	NaCl	$\text{CaO}\cdot \text{SO}^+$	H^+O	Insol.
64.3	1.5	8.4	1.3	22.5	1.65 = 90.65
32.2	24	33.3	—	8.87	1.35 = 99.72
26.15	66.66	2.63	—	4.05	0.40 = 99.80

See, further, CARBONATES (p. 268).

TUFA. On the composition of the tufas of Ichia, see C. W. Fuchs (*Jahrb. f. Mineralogie*, 1873, 429; *Jahresb. f. Chem.* 1872, 1168).

TUNGSTEN. Atomic Weight, 184.—Very exact experiments on this metal and its compounds have lately been made by Roscoe (*Proceedings of the Lit. and Phil. Soc. of Manchester*, January 23, 1872; *abst. Chem. Soc. J.* [2], x. 286).

Metallic Tungsten.—Tungstic oxide was prepared by decomposing commercial crystallised sodium tungstate with hydrochloric acid, dissolving the washed precipitate in ammonia, and igniting the recrystallised ammonium salt in an open crucible. Tungstic oxide thus obtained is a heavy powder, having a canary-yellow colour at ordinary temperatures, but acquiring a dark orange-colour when heated. The smallest admixture of sodium salt gives it a greenish colour; the same tint is also imparted to it by the action of light, which occasions a partial reduction. The pure metal obtained by heating this oxide to bright redness in a platinum or porcelain tube through which a stream of hydrogen is passed, is a granular powder having a light grey colour and strong lustre. By oxidation, it increases in weight by 26.01 p.c.; the atomic weight, 184, requires an increase of 26.09 p.c.

To obtain exact determinations of the atomic weight, the trioxide prepared from the oxychloride, to be presently described, was ignited in a platinum dish and then reduced by heating it in a stream of hydrogen. The atomic weight thence deduced was 183.84. Secondly, the hexchloride, WCl_6 , was heated in a stream of hydrogen, the resulting hydrochloric acid was determined, and the residual metallic tungsten weighed. This experiment gave $W = 184.25$, the mean of which and the preceding number is 184.04.

Chlorides. The hexchloride, WCl_6 , is formed by the action of chlorine on metallic tungsten, at a moderate heat, the combination being attended with ignition. The chlorine must be perfectly dry and free from oxygen, otherwise oxychloride will be formed at the same time, which it is not possible to separate from the chloride. The pure hexchloride forms a black-violet, crystalline sublimate, which, when considerable quantities are distilled, condenses in dark-red drops. The solidified mass decrepitates when cold; when pure, it does not alter in contact with moist air, but if the slightest trace of oxychloride is present, it absorbs moisture and decomposes. Water does not act on the pure chloride at temperatures below 60° , but the impure chloride is immediately decomposed by water even in the cold, into hydrochloric acid and yellow (or greenish-yellow) oxide. The chloride dissolves very easily in carbon sulphide, and separates out on cooling or evaporation of the dark red-brown solution, in brown hexagonal crystals. It melts at 276° (corr.), but the smallest contamination with oxychloride lowers the melting point by nearly 100° . It solidifies at 270° and under a pressure of 759 mm., boils constantly at 346.7° . The vapour-density, determined in sulphur-vapour (440°) was = 168.8; ($H = 1$) in mercury-vapour (350°) = 190.9. The calculated value is 198.6. Hence, it appears that dissociation takes place between 350° and 440° , and, in fact, direct experiments indicated a resolution of the hexchloride into pentachloride and free chlorine. This may explain the result obtained by Deville, who found the vapour-density to be 164.3 (at 350°), which was regarded as supporting the view suggested by Persoz, that tungsten is a pentad element with the atomic weight $Tu = 153.3$, its highest chloride being accordingly represented by the formula TuCl_5 (v. 899).

Pentachloride, WCl_5 .—This compound was prepared by partially reducing the hexchloride at a low temperature in a current of hydrogen, and then distilling off the volatile pentachloride from the non-volatile tungsten-compounds containing (less chlorine, formed at the same time. It crystallises in black, shining, highly deliquescent needles, which melt at 248° and boil at 275.6° . Vapour-density, obs. = 182.8 (in mercury-vapour); calc. = 180.7.

Tetrachloride and Dichloride.—The tetrachloride, WCl_4 , forms the non-volatile residue produced in the distillation of the hexchloride in hydrogen, provided that the temperature has not been allowed to rise too high. It is a soft, crystalline, highly hygroscopic powder, of a greyish-brown colour; it decomposes, when strongly heated, into the volatile pentachloride and dichloride which remains behind. The dichloride, WCl_2 , is a loose grey powder, without lustre or crystalline structure. It

is not permanent in the air, is dissolved in small quantity by water, but the greater part is decomposed into brown oxide (WO^2), and hydrochloric acid. It reduces nitric acid, forming ammonium nitrate:

Oxychlorides.—The *monoxychloride*, WCl^3 , is obtained by passing the vapour of the penta- or hex-chloride over the heated oxide or dioxychloride in a current of chlorine. It occurs in beautiful ruby-red crystals, which melt at 210.4° , and volatilise at 227.5° , and on exposure to air become at once coated with a yellow crust of the dioxychloride. Vapour-density in sulphur-vapour = 171.5° ; in mercury-vapour = 173° ; calc. = 171.

The *dioxychloride*, WO^2Cl^2 , is best obtained by the action of chlorine on the brown dioxide. It sublimes at a moderate heat, without previous fusion, in light yellow, shining, four-sided laminae, partly decomposing however into trioxide and monoxychloride.

Bromides. By the action of excess of bromine on tungsten, a *penta-* and not a *hexbromide* is obtained. The crystals of the pentabromide, WBr^5 , have a dark metallic lustre, resembling iodine; they undergo a slight decomposition by keeping, bromine being liberated. When the pentabromide is heated to 350° in a current of hydrogen, the *tribromide*, WBr^3 , is produced. Some slight indication of the formation of the compound WBr^4 was also observed, but it was not isolated.

Oxybromides.—The oxybromides, WOBr^4 and WO^2Br^2 , closely resemble the oxychlorides, and are prepared in a similar manner.

Iodide, WI^3 . Tungsten appears to form but one compound with iodine, the *diiodide*, which is produced when iodine vapour is passed over heated metallic tungsten, or over the brown oxide. It is a somewhat unstable compound, losing its iodine when heated in the air, and becoming converted into tungstic acid.

TURMERIC. On the colouring matter of turmeric, see CURCUMIN (p. 403).

TURPENTINE OIL. On the action of phosphonium iodide on turpentine oil, see HYDROCARBONS (p. 657).

On the formation of Cymene from turpentine oil, see CYMENE (p. 419).

The converse reaction does not appear to have been effected. According to Louguine (Deut. Chem. Ges. Ber. v. 730), cymene is not converted into turpentine oil, either by the action of sodium-amalgam on a solution of turpentine oil in aqueous alcohol mixed with a little ether, or by adding sodium to its alcoholic solution.

On the chemical relation of *phosphorus* to turpentine oil, and the action of the latter as an antidote in phosphorus poisoning, see Köhler a. Schimpf (Chem. Centr. 1872, 294; Jahresh. f. Chem. 1872, 242; Chem. Soc. J. [2], xi. 179).

TUTU. See CORIARIA (p. 391).

TYRITE. This mineral, from Helle near Arendal, has been analysed by Rammelsberg (Deut. Chem. Ges. Ber. iii. 926).

Nb^2O^5	SnO^2	YO	CeO	LaO DIO	FeO	UO^2	CaO	H^2O
45.00	1.05	30.0	5.74	3.51	1.48	6.52	2.46	4.88 = 100.54.

See also TANTALATES (p. 1146).

TYROSINE. According to Béchamp (Compt. rend. lxxiv. 115, 184), this substance is formed, together with leucine, in alcoholic fermentation induced by beer-yeast.

U

ULLMANNITE. *Antimonial and Arsenical Nickel-glance* (iv. 43).—Hemihedral crystals of this mineral from Lölling in Carinthia have been examined by Zepharovich (Wien. Akad. Ber. [1 Abth.], lx. 809). They exhibit the faces $\pm \frac{0}{2}$, ∞O , $\pm \frac{202}{2}$,

$\frac{20}{2}$ and $\frac{80}{2}$. Sp. gr. = 6.54–6.74. An analysis by W. Gintl gave the values A. which when corrected for admixed metallic bismuth and galena gave those in B. The
2nd Sup. 4 G

1186 ULTRAMARINE—URAMIDOBENZOIC ACID.

formula $\text{NiS.Ni}(\text{Sb}; \text{As})$, supposing $\frac{1}{10}$ of the antimony to be replaced by arsenic, requires the values O:

	S	Sb	As	Ni	Bi Pb	
A.	15.22	50.53	3.10	27.38	3.80	= 100.12
B.	15.73	52.56	3.23	28.48	—	= 100
C.	15.36	52.71	3.60	28.32	—	= 100

Tin-white to steel-grey ullmannite from the micaceous clay slate of the Rinkeberg in Carinthia exhibits the faces $\infty\text{O}\infty$, ∞O , and cleaves parallel to the cubic faces. Sp. gr. = 6.63. Its analysis gave

S	Sb	As	Ni*	
15.28	56.07	6.94	27.50	= 90.79.

* With traces of cobalt.

(M. v. Lill, *Jahrb. f. Min.* 1871, 641).

Ullmannite free from arsenic occurs, with spathic iron ore, in clefts of the limestone near Waldstein, in Carinthia, usually in laminar or granular aggregates, rarely in crystals. The crystals exhibit the combination $\infty\text{O}\infty$. O . ∞O , without any indication of hemihedral forms. Decomposition and mutual action of the mineral and the ground-mass is indicated by the presence of a calcic antimonate, $3\text{CaO}.2\text{Sb}^2\text{O}_3 + 6\text{H}^2\text{O}$, which occurs on the vein, partly as a greenish earthy mass, partly in pseudomorphous crystals of the form above described (Rumpf u. Ullik, *Jahrb. f. Min.* 1870, 355).

ULTRAMARINE. On the composition of Ultramarine, see Fürstenau (*Dingl. pol. J.* cci. 176; *Jahresb. f. Chem.* 1871, 1019); Stein (*J. pr. Chem.* [2], iii. 39; *Chem. Soc. J.* [2], ix. 166; *Jahresb.* 1871, 1020). On the blue-burning of ultramarine direct from the raw mass: Fürstenau (*Dingl. cii.* 446; *Jahresb.* 1871, 1019). On the supposed incapability of Potash to form Ultramarine; Stein (*J. pr. Chem.* [2], iii. 137; *Chem. Soc. J.* [2], ix. 451).

UMBELLIFERONE, $\text{C}^8\text{H}^4\text{O}^2$. From experiments by Kachler, reported by Hlasiwetz (*Deut. Chem. Ges. Ber.* [2], ix. 550), it appears that umbelliferone, heated to 100° with acetyl chloride, is converted into monacetyl-umbelliferone, $\text{C}^8\text{H}^4(\text{C}^2\text{H}^3\text{O})\text{O}^2$, which, after recrystallisation from dilute alcohol, forms small colourless needles, nearly insoluble in water, easily soluble in warm alcohol, and fluorescent, though somewhat less strongly than pure umbelliferone.

Umbelliferone boiled with strong potash yields resorcin, together with carbonic and formic acids. Hlasiwetz represents it by the formula $\text{C}^8\text{H}^4(\text{CH}^3\text{O})^2(\text{C}^2\text{O}^2\text{H})$.

URAMIDOBENZOIC ACID, $\text{C}^8\text{H}^4\text{N}^2\text{O}^3$. This acid, discovered by Griess (1st *Suppl.* 318), may be produced by melting together urea and amidobenzoic acid:

and its ethylic ether in like manner by fusing urea with ethylic amidobenzoate (see **BENZOIC ACID DERIVATIVES**, p. 166).

Nitro-uramidobenzoic Acids (Griess, *J. pr. Chem.* [2], v. 227; *Deut. Chem. Ges. Ber.* v. 192; *Proc. Roy. Soc.* xx. 168). The dinitro-uramidobenzoic acid, $\text{C}^8\text{H}^2(\text{NO}^2)^2\text{O}^3$, formed by the action of strong nitric acid on uramidobenzoic acid (1st *Suppl.* 318), is a mixture of three isomeric acids, which cannot be separated from each other, owing to the great similarity of their properties.

When the solution of the three dinitro-acids in aqueous ammonia is boiled for some time, they are converted into the mono-nitro-acids:

By adding barium chloride to the hot solution on cooling, the barium salt of the β -acid is separated in needle-shaped crystals. On concentrating the mother-liquor of this salt by evaporation, the salt of the α -acid separates in microscopic needles; the barium salt of the third acid is obtained by boiling the mother-liquor from the previous salt to dryness, and washing the residue with water. It crystallises from hot water in bright yellow scales.

The three acids set free from the barium salts by means of hydrochloric acid have the following properties:

α -Nitro-uramidobenzoic acid, $\text{C}^8\text{H}^3(\text{NO}^2)\text{N}^2\text{O}^3$, crystallises in bright yellow needles or small plates; it is very slightly soluble in cold water, sparingly in hot, and freely in hot alcohol.

β -Nitro-uramidobenzoic acid crystallises in slender yellow needles, and is also much more freely soluble in alcohol than in water.

γ-Nitro-uramidobenzoic acid is very slightly soluble in all neutral solvents, and forms small yellow scales. When the free acid and its salts are boiled with water for a considerable time, the following decomposition takes place:

The α - and β -acids are reduced by tin and hydrochloric acid to the amido-acids. *α-Amido-uramidobenzoic acid*, $\text{C}^6\text{H}^4(\text{NH}^2)\text{N}^2\text{O}^3$, is but slightly soluble in hot water, and less so in alcohol; it forms a white silver salt, $\text{C}^6\text{H}^4\text{N}^2\text{O}^3\text{Ag}$, and a hydrochloride, $\text{C}^6\text{H}^4\text{N}^2\text{O}^3\cdot\text{HCl}$, which is almost insoluble, even in very dilute hydrochloric acid. *β-Amido-uramidobenzoic acid* is very little soluble in water, and, curiously enough, does not combine with acids, but forms metallic salts having the formula $\text{C}^6\text{H}^4\text{N}^2\text{O}^3\text{M}$. On boiling this acid with hydrochloric acid or baryta-water, it gives off ammonia, and a new acid is formed, which may be regarded as amidobenzoic acid, in which one atom of hydrogen is replaced by $(\text{CO})\text{N}$, and may therefore be called *β-amidocarboxamidobenzoic acid*, $\text{C}^6\text{H}^4(\text{NH}^2)(\text{CO}(\text{N}))\text{O}^2$; this acid forms white nodules insoluble in all neutral solvents.

γ-Nitro-uramidobenzoic acid is not reduced by the action of tin and hydrochloric acid, but undergoes the following decomposition:—

The new compound is *γ-amidocarboxamidobenzoic acid*. It forms white needles, which are almost insoluble in water, alcohol, and ether.

By the action of nitric acid, the mononitro-acids are again converted into the dinitro-acids, which can thus be obtained in the pure state. They closely resemble one another, forming yellowish white needles, which are readily soluble in alcohol and ether, but scarcely soluble in cold water. The barium-salts of the α - and β -acids are very sparingly soluble; that of the former crystallises in microscopic needles, that of the latter is amorphous. Barium *γ*-dinitro-uramidobenzoate is somewhat more readily soluble, and forms long slender yellow needles.

The three dinitro-acids are converted into the corresponding nitro-amido-benzoic acids, when their aqueous solutions are boiled for a considerable time:

α-Nitro-amidobenzoic acid, $\text{C}^6\text{H}^4(\text{NO}^2)(\text{NH}^2)\text{O}^2$, is readily soluble in hot alcohol, but only sparingly soluble in water, and forms yellow prisms. The barium salt, $(\text{C}^6\text{H}^3\text{N}^2\text{O}^3)^2\text{Ba} + 3\text{H}^2\text{O}$, crystallises in yellowish-red needles, and is readily soluble in water.

β-Nitro-amidobenzoic acid crystallises from hot alcohol in clusters of glistening, yellowish-red needles, or small plates. When gently heated it sublimes in shining rhombic plates, without previous melting. Its barium salt, $(\text{C}^6\text{H}^3\text{N}^2\text{O}^3)^2\text{Ba} + 2\text{H}^2\text{O}$, is only slightly soluble in boiling water, and crystallises in bright, yellowish-red prisms.

γ-Nitro-amidobenzoic acid is very readily soluble in hot water and in cold alcohol and ether. It forms yellow prisms, which melt when heated to a brown oil, and decompose with slight explosion at a higher temperature. The barium salt, $(\text{C}^6\text{H}^3\text{N}^2\text{O}^3)^2\text{Ba} + 7\text{H}^2\text{O}$, is easily soluble, even in cold water.

On gently warming these three nitro-amido-acids with tin and hydrochloric acid, the corresponding diamido-acids are formed. *α-Diamidobenzoic acid*, $\text{C}^6\text{H}^4(\text{NH}^2)^2\text{O}^2$, is sparingly soluble in hot water, and crystallises in minute but well-defined short prisms. It is remarkable for the extremely sparing solubility of its sulphate, $\text{C}^6\text{H}^4\text{N}^2\text{O}^3\cdot\text{SO}^4\text{H}^2$.

The *β-diamido-acid* is rather readily soluble in hot water, and forms pale yellow plates. Its sulphate has the composition $[\text{C}^6\text{H}^3(\text{NH}^2)^2\text{O}^3]^2\text{SO}^4\text{H}^2$, and is a little more soluble than that of the α -acid. The *γ-acid* crystallises in long, yellowish-white needles; the sulphate, $(\text{C}^6\text{H}^3\text{N}^2\text{O}^3)^2\text{SO}^4\text{H}^2 + 1\frac{1}{2}\text{H}^2\text{O}$, forms white, six-sided tables, and is almost as insoluble as that of the α -acid.

When the α -diamido-acid is dissolved in warm, dilute, hydrochloric acid, insufficient to dissolve the whole, and the filtered solution is mixed with sodium nitrite, an explosive compound, crystallising in long needles, is formed. This body has no acid properties, but combines readily with acids, forming well-crystallised salts. Its formula is probably $\text{C}^6\text{H}^4\text{N}^2\text{O}^4$. In presence of free hydrochloric acid, this basic compound is not formed, but nitrogen is evolved, and an amorphous reddish-brown acid is deposited.

The hydrochlorides of the two other amido-acids behave differently with sodium nitrite; they both yield *azo-acids*. That from the β -compound is very sparingly soluble in water, and forms white, short needles, which, when heated in the dry state, melt and blacken; a small portion subliming, but the greater part being completely

decomposed. The barium salt, $(C^6H^4N^2O^4)^2Ba + 4H^2O$, is readily soluble in hot water, and crystallises in slender, colourless needles. The γ -*azo*-acid crystallises in long, hair-like, silky needles. It is more soluble than the β -acid; when gently heated it melts to a yellow oil, with partial sublimation; at a higher temperature it decomposes, with a slight explosion. The white needles of its barium salt, $(C^6H^4N^2O^4)^2Ba + 2H^2O$, are only sparingly soluble in hot water.

When either of the diamido-acids is submitted to dry distillation, it splits up into carbon dioxide and a phenylene-diamine. That from the α -acid is identical with the diphenylamine which is obtained from the nitroaniline prepared from substituted anilides. The β and γ -acids yield one and the same phenylene-diamine, which, however, is not identical with that derived from dinitrobenzene, but is a new isomeric modification. It crystallises from hot water in white, rectangular, four-sided tables, melting at 99° , and boiling at about 252° . The *sulphate*, $C^6H^4(NH^2)^2SO^4H^2 + 1\frac{1}{2}H^2O$, crystallises in pearly scales. The *platinum salt* is precipitated in the form of brownish-red needles. When ferric chloride is added to a solution of the base in hydrochloric acid, ruby-red needles are formed, consisting of the hydrochloride of a new base, which probably has the composition $C^{12}H^4N^4$.

There is a fourth diamidobenzoic acid known, which Voit has obtained by reducing dinitrobenzoic acid. This body is distinguished from its isomerides, not only by its physical properties, but especially by not yielding a volatile base when submitted to distillation, being completely carbonised, with evolution of ammonia.

URAMIDODINITROPHENYLIC ACID, $C^6H^4N^2O^4 = C^6H^4(CO^2H^2N^2)(NO^2)^2O$ (Griss, *J. pr. Chem.* [2], v. 1). When picramic acid is added to an equal weight of melted urea, ammonia is evolved, and the whole soon solidifies to a brown mass; and on dissolving this mass in dilute ammonia, and adding hydrochloric acid to the solution, uramidodinitrophenylic acid is precipitated, and may be purified by repeated crystallisation from boiling water. Its formation is thus represented:—

Uramidodinitrophenylic acid dissolves with difficulty in boiling water, and crystallises out on cooling in long narrow plates of a bright yellow colour. It is readily soluble in hot alcohol, and yields crystalline salts with bases. Its barium salt forms blood-red needles, and its silver salt, $C^6H^4N^2O^4.Ag$, is a reddish-yellow amorphous precipitate.

Amido-uramidodinitrophenylic acid, $C^6H^4N^2O^4 = C^6H^4(NH^2)\left[\begin{smallmatrix} CO \\ H^2 \end{smallmatrix}\right]N^2(NO^2)^2O$, is prepared from the acid just described by treating it with ammonium sulphide. The blood-red solution is carefully decomposed by hydrochloric acid, and the precipitate treated with hot water. After separation of the sulphur by filtration, the solution is first rendered alkaline by ammonia, and then acidified with acetic acid. The acid thus obtained crystallises in reddish-brown needles, which are soluble with difficulty both in hot water and alcohol, and scarcely soluble in ether. It forms compounds both with acids and bases, the latter being very stable. The *hydrochloride*, $C^6H^4N^2O^4.HCl$, is precipitated in white glistening scales on adding concentrated hydrochloric acid to a solution of the new acid in warm dilute hydrochloric acid. It is readily soluble in pure water. On mixing a hot concentrated ammoniacal solution of amido-uramidodinitrophenylic acid with barium chloride, the *barium compound*, $(C^6H^4N^2O^4)^2Ba + 3\frac{1}{2}H^2O$, is precipitated in steel-blue glistening needles, which dissolve freely in hot, sparingly in cold water.

Amidocarboxamidodinitrophenylic acid, $C^6H^4N^2O^4 = C^6H^4(NH^2)[(CO)N](NO^2)^2O$.—On boiling the hydrochloric acid solution of amido-uramidodinitrophenylic acid for a quarter of an hour, ammonia is eliminated, and solidifies on cooling to a pulp of crystals, consisting of amido-carboxamidodinitrophenylic acid. This acid dissolves with difficulty in boiling water, and crystallises therefrom in golden-yellow needles. It is much more soluble in alcohol than in water, but only slightly soluble in ether. Like the preceding it combines both with acids and with bases, but the former compounds are very unstable. The *hydrochloride*, $C^6H^4N^2O^4.HCl + H^2O$, formed by dissolving the acid in hot moderately concentrated hydrochloric acid, crystallises in white glistening plates, which at 100° lose both their water and hydrochloric acid, leaving pure amidocarboxamidodinitrophenylic acid. The *barium salt*, $(C^6H^4N^2O^4)^2Ba$, forms yellow difficultly soluble needles.

Diamidocarboxamidodinitrophenylic acid, $C^6H^4N^2O^4 = C^6H^4(NH^2)[(CO)N]O$.—Amidocarboxamidodinitrophenylic acid, when treated with tin and hydrochloric acid, yields a very difficultly soluble stannochloride of the diamidated acid. On decomposing this salt with sulphuretted hydrogen, the hydrochloride $C^6H^4N^2O^4.HCl$ is obtained in white plates, which become brown when exposed to the air in the moist state. The

free acid, prepared from this compound by the addition of ammonia to its solution in boiling water, forms needles which are difficult to obtain colourless, as they oxidise and become brown on exposure to the air. This acid is but very slightly soluble in boiling water, and still less so in alcohol or ether. It combines with mineral acids, forming monacid compounds, and dissolves in potash-solution and baryta-water, but is reprecipitated by carbonic acid.

URAMIDODRACYLIC ACID, $C^6H^3N^2O^4$, is formed in urea and para-amidobenzoic acid in the same manner as uramidobenzoic acid from urea and amidobenzoic acid (p. 166).

URAMIDOHIPPURIC ACID, $C^{10}H^{11}N^2O^4$, is the chief product obtained by fusing urea with amidhippuric acid. It is very soluble in hot water, and crystallises therefrom in nodules. Its silver salt, $C^{10}H^{11}N^2O^4Ag$, is a white crystalline precipitate. By prolonged boiling with strong hydrochloric acid, uramidhippuric acid is resolved into uramidobenzoic acid and glycerin:

When heated by itself it does not yield carboxamidhippuric acid, nevertheless this acid is formed in small quantity in the preparation of uramidhippuric acid. It is very slightly soluble in water, and crystallises therefrom in narrow shining laminae or six-sided tablets. Its barium salt, $C^{10}H^{11}N^2O^4Ba$, crystallises in needles (Griess, *J. pr. Chem.* [2], i. 233).

URAMIDODRACYLIC ACID, $C^6H^3N^2O^4$, is formed in like manner by fusing urea with anthranilic acid. When heated to 200° it splits up, like uramidobenzoic acid (p. 166), into urea and carboxamidosalicylic acid, $C^8H^7N^2O^4$:

This latter acid is nearly insoluble in water and in alcohol, and separates from its ammoniacal solution, on acidulation with hydrochloric acid, in white microscopic needles (Griess, *loc. cit.*).

URANIUM. Atomic weight.—Mendelejeff doubles the usually received atomic weight of this metal, making it 240, and regarding uranium as a hexad analogous to chromium. The reasons for this change are given in his memoir 'Ueber die periodische Gesetzmässigkeit der Chemischen Elemente' (*Ann. Ch. Pharm., Suppl.* viii. 178).

According to the atomic weight hitherto adopted (120), uranium is regarded as a metal of the iron-group, forming the oxides UO , U^2O^3 , U^3O^4 ; but it differs from the metals of this group in several important characters, viz.: that it has a high specific gravity (18.4), and forms a volatile chloride (UCl^4); that uranic oxide does not form salts of the type UCl^4 or U^2Cl^6 , but only of the type UOX (X denoting an acid radicle, Cl , NO^2 , &c.); and that although uranium has a greater atomic weight than iron, it is less easily reducible, and its oxides are weaker bases than the corresponding iron oxides. Moreover, the uranous salts are not isomorphous with those of the magnesium series, as they should be if uranous oxide were a monoxide, UO . Uranous sulphate, $UrS^2O^6 + 8H^2O$, crystallises in the monoclinic system, and forms, according to Rammelsberg's experiments, the double salts $\frac{2(NH^4)^2SO^4}{UrS^2O^6}$ and $\frac{K^2SO^4}{UrS^2O^6}$, to which there are no analogues among the sulphates of the magnesian metals (see further, Rammelsberg, *Deut. Chem. Ges. Ber.* v. 1003). On the other hand, uranium resembles the hexad metals, tungsten and molybdenum, in forming a *pentachloride* (p. 1190).

An apparent objection to the doubling of the atomic weight of uranium is, that its specific heat, 0.6190, when multiplied by 240, makes the atomic heat 14.86, which is more than double the normal value; but the force of this objection is considerably diminished by the fact that the specific heat of metallic uranium has not yet been accurately determined (see HEAT, iii. 30).

The following table exhibits the formulae of the chlorides, oxides, &c., of uranium, according to the old and new atomic weights:

U = 120

U = 240

Uranous Compounds.

UCl^3 ; UO
 $U^2SO^4 \cdot 2H^2O$
 $K^2U^2(SO^4)^2 \cdot H^2O$

UCl^4 ; U^2O^3
 $U^2(SO^4)^2 \cdot 4H^2O$
 $K^2U^2(SO^4)^2 \cdot H^2O$

Uranous-uranic Oxide.

$U^2O^3 = UO \cdot U^2O^3$

$U^2O^3 = UO^2 \cdot 2UO^2$

U = 120

U = 240

Uranic or Uranyl Compounds.

Estimation and Separation.—On the titration of Uranous Solutions, see Follenius (*Zeitschr. anal. Chem.* 1872, 179).

On the Separation of Uranic from Ferric Oxide, and on the estimation of Phosphoric acid by means of Uranium, see H. Rheineck (*Dingl. pol. J.* cc. 383; *Chem. Soc. J.* [2], x. 178). On the latter point see also p. 968 of this volume.

On the working up of Uranium-residues after estimation of Phosphoric acid, see W. Jani (*Chem. News*, xxiii. 220; *Chem. Soc. J.* [2], ix. 586).

Pentachloride, UCl_5 [U = 240] (Roscoe, *Chem. Soc. J.* [2], xii. 933). This compound is obtained, together with the well-known tetrachloride or uranous chloride, UCl_4 , by passing excess of dry chlorine over a moderately heated mixture of charcoal with any of the oxides of uranium, or with the oxychloride, $\text{UO}^{\text{O}}\text{Cl}_2$. It exists in two distinct forms according as it is produced slowly or quickly. When the current of chlorine is slow, the pentachloride of uranium forms long, dark, needle-shaped crystals, which reflect light with a green metallic lustre, but appear of a splendid ruby-red colour when viewed by transmitted light. If the rate at which the chlorine passes is rapid, the pentachloride is deposited in the form of a light brown, mobile powder. The magnificent octohedral crystals of the tetrachloride are always deposited in quantity in that part of the tube nearest to the heated mixture; then the black needle-shaped crystals of pentachloride are formed, mixed with more or less of the brown powder, which is generally carried for a considerable distance along the tube. Both the black needles and the brown powder are extremely hygroscopic, yielding, on exposure to the air for a few minutes, yellowish green liquids, and hissing and giving off fumes of hydrochloric acid when thrown into water.

The mean of four analyses of this compound gave 57.47 p.c. uranium and 42.52 chlorine (= 99.79), the formula UCl_5 requiring 57.49 uranium and 42.51 chlorine.

Uranium-pentachloride cannot be volatilised without partial decomposition, either when heated alone or in an atmosphere of chlorine or of carbon dioxide, uranium tetrachloride and free chlorine being formed. This dissociation begins in an atmosphere of carbon dioxide at a temperature of 120° , and is completed at 235° , when the percentage of chlorine contained in the residue shows that one-fifth of the chlorine has been driven off. The tetrachloride, when similarly heated, loses no chlorine.

The pentachloride heated to redness in a current of dry ammonia yields a black nitride.

Uranates. Thallous oxide added to uranium solutions forms a yellow precipitate of thallium uranate analogous to the uranates of the alkali-metals (C. Bolton, *American Chemist*, 1872, ii. 466).

Tetraethylammonium Uranate, $(\text{C}^{\text{H}}_3)_4\text{NO} \cdot \text{UO}^{\text{O}} + 3\text{H}^{\text{O}}$, is formed on adding a solution of tetraethylammonium hydroxide to a solution of uranic nitrate, as a yellow precipitate very much like that produced by ammonia, and shrinking up in drying to a brownish-red, amorphous, semivitreous mass, which yields a yellow powder. It dissolves easily in dilute acids. The acetic acid solution yields on evaporation small crystals, probably consisting of a double acetate of uranium and tetraethylammonium. On dissolving the salt in strong nitric acid, decomposition takes place (Bolton, *loc. cit.*)

On *Uranic Acetates and Sulphates*, see pp. 7, 1140.

Uranic Arsenates. Four of these minerals found, together with a bismuth uranate (uranospherite) in the White Hart Mine, near Schneeberg in Saxony, have been described by A. Weisbach (*Mineralogische Mittheilungen*, 1872, 181; *Jahresb. f. Mineralogie*, 1873, 296), and analysed by Cl. Winkler, with the following mean results:

	As^{O}_2	UO^{O}	B^{O}_2	CuO	CaO	H^{O}	
Trögerite	18.98	63.21	—	—	—	17.21	= 99.30
Walpurgin	12.45	80.38	20.41	—	—	4.48	= 97.72
Zemserite	20.94	55.86	—	7.49	—	15.68	= 99.97
Uranospinitite	15.37	59.18	—	—	6.47	18.19	= 100.21
Uranospherite	—	50.60	44.23	—	—	5.16	= 99.99

These analyses lead to the following formulae:

Trögerite	3UO ³ . As ² O ³ + 12H ² O.
Walpurgin	5Bi ² O ³ . As ² O ³ + 3UO ³ . As ² O ³ + 10H ² O.
Zeunerite	CuO . 2UO ³ . As ² O ³ + 8H ² O.
Uranospinito	CaO . 2UO ³ . As ² O ³ + 8H ² O.
Uranosphærite	Bi ² O ³ . UO ³ + H ² O.

Trögerite forms lemon-yellow monoclinic crystals, scaly by predominance of the clinopinacoid, bearing a general resemblance to the crystals of heulandite, and, like the latter, having a nacreous lustre on the clinopinacoid faces.

Walpurgin is mostly lemon-yellow, honey-yellow, or wax-yellow, sometimes however straw-yellow. The crystals have the character of the ordinary crystallisation of gypsum. The most highly developed faces are, as in trögerite, those of the clinopinacoid, but they have an adamantine rather than a nacreous lustre. The projecting summits of the crystals are often serrated.

Zeunerite forms emerald-green or apple-green quadratic crystals, of pyramidal, tabular, or scaly character, consisting of the prism, the base, and a very acute pyramid. The basal faces have a nacreous lustre, and correspond with the direction of a perfect cleavage. Zeunerite is, therefore, not only analogous in chemical composition to ordinary copper uranium mica (torbernite), but likewise isomorphous and isoclastic with it. The two minerals are, indeed, deceptively similar to one another in appearance.

Uranospinito forms siskin-green scaly crystals having a square or rectangular transverse section; their optical characters show that they belong to the rhombic system. The cleavage-planes run parallel to the plane of the scales, and notwithstanding the perfection of the cleavage, they exhibit but little tendency to nacreous lustre. Uranospinito probably belongs also to the family of the uranium micas, being indeed the arsenate analogous to lime-uranite (autinite).

Uranosphærite forms orange-yellow or egg-yellow nodules, roughly or finely drusy, and having a dull or faint satiny lustre. Under the microscope the drusy surface resolves itself into an aggregate of acutely pyramidal crystals, sticking out from the nodules like the bristles of a hedgehog. The fractured surface exhibits a fatty lustre and a concentrically scaly structure.

All five species are somewhat lighter-coloured when pulverised, and are intermediate in hardness between gypsum and calcspar. Their specific gravities, according to the mean of several determinations at 9°, are—

Trögerite	Walpurgin	Zeunerite	Uranospinito	Uranosphærite
3.23	5.64	3.53	3.45	6.36

Trögerite is therefore the lightest and uranosphærite the heaviest of the five.

With regard to succession in time, walpurgin and trögerite appear to be the oldest formations; then follows uranosphærite, then zeunerite, and lastly uranospinito.

URANOPHANE. A hydrated uranic silicate from Kupferberg in Silesia, having the following composition:

SiO ²	UO ³	Al ² O ³	CaO	MgO	K ² O	H ² O
17.08	53.38	6.10	5.07	1.46	1.85	15.11 = 100

(Websky, *Jahresb. f. Chem.* 1870, 1304).

URANOTIL. This is also a uranic silicate chemically and crystallo-graphically allied to uranophane, occurring in slender needles in the druses of the quartz which covers the fluor spar of Wilsendorf in Bavaria. It is lemon-yellow, blackens when heated, and dissolves in hydrochloric acid, with separation of flocculent silica. According to Zepharovich, the needles are rhombic and exhibit the faces ∞P . ∞P_{∞} . mP_{∞} . The angle ∞P is nearly 164°. Sp. gr. = 3.95. The mean of three analyses (A) by Boricky (*Jahresb. f. Mineralogie*, 1879, 780), and the analyses B and C by Weissbach (*ibid.* 1873, 296) lead to the formula $UO^3.SiO^2 + H^2O$.

	SiO ²	P ² O ⁵	UO ³	Al ² O ³ .Fe ² O ³	CaO	H ² O	
A.	13.78	0.45	66.75	0.51	5.27	12.67	= 99.43
B.	13.02	—	63.93	3.03	5.13	14.55	= 99.66
C.	14.48	—	62.84	2.88	5.19	13.79	= 99.48

UREA, CH²N²O. *Formation.*—Campani (*Gazz. chim. ital.*, i. 472) has observed the formation of urea by the slow evaporation of aqueous hydrocyanic acid.

By Oxidation of Proteids.—Béchamp, in 1858 (*Ann. Chim. Phys.* [3], xlviii. 348) described the formation of urea from albumin by the action of potassium permanganate in alkaline solution. Stædeler (*J. pr. Chem.* lxxii. 261) and O. Loew (*ibid.* [2], ii.

289), in repeating Béchamp's experiments, did not succeed in obtaining urea. Béchamp however (*Compt. rend.* lxx. 866) maintains the correctness of his former statement, and describes more fully the process by which he obtained urea from albumin. 60-70 grams of potassium permanganate are added to 10 grams of pure dry white of egg suspended in 200-300 grams of water, and the liquid is digested on a water-bath at 60°-80°. The reaction sets in after a while, with frothing, and as soon as this is over, the liquid is filtered, the precipitate washed, and the filtrate precipitated with basic lead acetate, not in excess. The lead is then removed by hydrogen sulphide, and mercuric nitrate is added to the filtered solution, which is kept nearly neutral with baryta-water till the addition of the baryta-water produces a yellow precipitate. This precipitate is suspended in water, decomposed with hydrogen sulphide; the acid filtrate saturated with barium carbonate and evaporated to dryness on the water-bath; and the residue is exhausted with alcohol of 94 p.c. The amorphous residue of the alcoholic extract gives with nitric acid crystalline laminae, which evolve gas when treated in the cold with Miller's reagents. E. Ritter (*Bull. Soc. Chim.* [2], xvi. 32) confirms Béchamp's statement, and gives the following as the quantities of urea obtained by oxidation of different proteids:

30 grams of moist Albumin gave 0.09 gram urea.

" " " Fibrin " 0.07

" " " Gluten " 0.29, 0.31, and 0.21 gram urea.

On the Formation of Urea in the Animal Organism, see Schulzen a. Nencki (*Zeitsch. f. Biologie*, viii. 124; *Chem. Soc. J.* [2], x. 833).

On the question whether the formation of Urea takes place in the Blood or in the Kidneys, see Gréhan (*Jahresb. f. Chem.* 1872, 916).

O. Popp (*Ann. Ch. Pharm.* clvi. 88) has obtained from fresh pig's bile, crystals which he regards as urea.

Reactions. 1. With Nitrous Acid.—The decomposition of urea by nitrous acid is generally represented by the equation:

whereas Wöhler a. Liebig some years ago represented it by the equation:

According to Claus (*Deut. Chem. Ges. Ber.* iv. 140) the reaction (2) takes place when nitrous acid is added to a solution of urea in the cold, in the proportion of 1 mol. N^+O^+ to 2 mols. urea; reaction (1), on the other hand, when nitrous acid is gradually added to a hot solution of urea. This arises, as Wöhler a. Liebig showed, from the fact that 1 mol. urea and 1 mol. nitrous acid are resolved in the cold into cyanic acid and ammonium nitrite:

and that, on warming the solution, the ammonium nitrite is resolved into water and nitrogen, while the cyanic acid, by reacting with the water, is resolved into ammonia and carbon dioxide. When, on the other hand, the nitrous acid is gradually added, the ammonium carbonate formed in the first instance is resolved into nitrogen, carbon dioxide, and water. Equation (2) is likewise realised when a stronger acid is added to the liquid, the ammonia salt of this acid being then produced.

2. With Phosgene.—Urea, heated with excess of liquid phosgene, is converted into carbonyl-diurea, $\text{C}^+\text{H}^+\text{N}^+\text{O}^+$, which, by further action, yields hydrochloric acid and a mixture of cyanic, diacyanic, and cyanuric acids (p. 262).

On the action of Urea Nitrate on Benzyl Alcohol, see p. 178.

On the Detection of Urea in Blood and in the Tissues, see Perls (*Zeitschr. anal. Chem.* ix. 421; *Jahresb. f. Chem.* 1871, 1052).

On the Estimation of Urea by means of Sodium Hypobromite, see Hüfner (*J. pr. Chem.* [2], iii. 1; *Chem. Soc. J.* [2], ix. 162).

Sulpho-ureas. See SULPHOCARBAMIDES (p. 1116).

URIC ACID. $\text{C}^+\text{H}^+\text{N}^+\text{O}^+$. On the constitution of this acid, see Kolb (*J. pr. Chem.* [2], i. 184; Strecker, *Ann. Ch. Pharm.* clv. 177; also *Jahresb. f. Chem.* 1870, 724).

On the Estimation of Uric acid in Urine, see E. Salkowski (*Pflüger's Archiv. f. Phys.* v. 210; *Deut. Chem. Ges. Ber.* v. 410; *Chem. Soc. J.* [2], x. 383, 844; H. Schwarzen, *Ann. Chem. Pharm.* clxiii. 163; *Deut. Chem. Ges. Ber.* v. 316; *Chem. Soc. J.* [2], x. 844, 929; R. Maly, *Pflüger's Archiv.* v. 301; *Chem. Soc. J.* [2], ix. 1123).

URIC. (Neubauer a. Vogel, *Anleitung zur qual. u. quant. Anal. d. Harns.* 6. Auflage). Thudichum (*Centr. f. d. Med. Wissen.* 1870, No. 13, 14; *Chem. Soc. J.* [2], viii. 132) has described an amorphous nitrogenised acid, $\text{C}^+\text{H}^+\text{N}^+\text{O}^+$, which he names cryptophanic, as a normal constituent of human urine (see *lit. Suppl.* 213). See

observers have however completely failed to prepare this acid, and are agreed that Thudiechum's calcic cryptophanate is a variable mixture of still unknown bodies, whose indefiniteness and impurities render it impossible to make as yet any definite assertion as to their composition (see Fucher, *Centr. f. d. Med. Wissen.* 1871, 22, and Liversidge, *Journ. of Anat. a. Phys.* May 1872). Thudiechum has however repeated his statement (*Centr. f. d. Med. Wissen.* 1872, 81), and also described another acid with the composition $C^{11}H^{10}N^{10}O$, which he calls *paraphanic*, as existing in the mother-liquor from which the calcic cryptophanate has been precipitated. He also believes that he has detected acetic acid as a normal constituent of human urine (*Deut. Chem. Ges. Ber.* 1870, 578).

Roberts (*Mem. Manch. Lit. a. Phil. Soc.* 1862) has given a simple method of estimating the quantity of sugar in urine, which is extremely useful as being sufficiently accurate for clinical purposes. The specific gravity of the urine is taken, and a little dried yeast is added to it; it is then set aside in a warm place for 24 hours, and its specific gravity is again taken; the number of degrees of specific gravity which is lost answers to one grain of grape-sugar in a fluid ounce of urine, or multiplied by 0.23, will give the number of parts of sugar in 100 of the urine. According to Hensley, the quantity reckoned in this way is, on theoretical grounds, about $\frac{1}{8}$ too great. Manassein finds that for practical purposes it may be regarded as very nearly exact (*Deutsches. Arch. f. Klin. Med.* 1872, 73); the number which he gives as multiplier is 0.219. With reference to the detection of grape-sugar in urine by means of Trömmner's test, it is worthy of note that the reaction is much clearer if the urine be previously filtered through animal charcoal; in many cases indeed, even when a considerable quantity of glucose is present, no reduction will occur on boiling, unless this precaution be taken previously. The animal charcoal holds back a very small quantity of the glucose.

The exact places in the body at which urea is formed are still far from accurately known. It has already been pointed out that there is considerable reason to believe that a good deal is formed in the liver (see GRAYCOCK), but many observers still maintain that all, or nearly all, is formed in the kidneys, from less highly oxidised nitrogenous compounds brought to them by the blood. Voit has shown that creatine when introduced into the blood passes out in the urine as creatinine, and not as urea, and he has also shown that, after extirpation of the kidneys, just as much urea accumulates in the blood and organs as after simple ligature of the ureters (*Sitz. d. Kön. bayer. Acad. d. Wiss.* 1867, i. 364; see also Gréhant, *Journ. de l'Anat. et de la Phys.* 1870, 318). These facts very strongly support the view that urea is simply separated from the blood in the kidneys. It has also now been well established that muscular work has little or no effect on the excretion of nitrogen in the urine (see MUSCULAR TISSUE), but that, on the other hand, the quantity of proteid matters taken in the food has a very important influence. Possibly in the latter case a good deal of the urea proceeds almost directly from the food, for it has been shown that leucine, which is largely formed in the small intestine from proteid foods, is, when given to an animal, excreted for the most part as urea (Schultzen n. Nencki, *Zeitsch. f. Biologie*, 1872, 189). Glycine and glycocine, when administered to an animal, also increase the quantity of urea excreted by it. There is also much reason to believe that a good deal of urea is formed in the spleen (Gscheidlen, *Ueber den Ursprung des Harnstoff's im Thierkörper*, Leipzig, 1871).

Reysson (*Journ. pour l'Anat. et Phys.* p. Robin. 1872, 388) has suggested that the acidity of normal human urine is not due, as generally supposed, to the presence of acid phosphates, but rather to free uric and hippuric acids, since he finds that those bodies cannot decompose neutral sodic phosphate at ordinary temperatures.

H. N. M.

UROBILIN. See BILE-PIGMENTS (p. 190).

UROSULPHINIC ACID, $C^4H^4N^1SO^2$. This name is given by Nencki (*Deut. Chem. Ges. Ber.* v. 45) to an acid produced by the action of strong sulphuric acid on sulpho-pseudo-uric acid (p. 1125) at a temperature not exceeding 160° . The substance precipitated by water is dissolved in ammonia, reprecipitated by hydrochloric acid, and the washed and dried precipitate is boiled with a weak alkaline-ley. The alkali salt then separates from the filtrate in white needles containing water, and may be purified by repeated crystallisation. The acid precipitated from it by hydrochloric acid and dried at 140° has the composition above stated.

Urosulphinic acid is intermediate in its chemical relations between uric acid and xanthine. It is a weak monobasic acid, and is precipitated from its alkaline solution by carbonic acid in characteristic spherical forms. The sulphur is not abstracted from it by metallic oxides at the boiling heat or even at higher temperatures. The acid is decomposed by prolonged boiling of its alkaline solution, but it is not altered by heat.

ing it to 200° with water for five hours. Sodium-amalgam converts it into a sulphuretted compound which dissolves easily in hot water and crystallises in silky needles.

UROXANIC ACID. This acid, which Städeler obtained by the action of potash on uric acid (v. 969), has been further examined by Strecker (*Ann. Ch. Pharm.* clv. 177). To prepare it, uric acid was dissolved in potash-ley, and left to itself, in a flask fitted with a potash tube. In about six months the uric acid was decomposed, and the solution, cooled to between -5° and -10°, deposited crystallised potassium uroxanate, from which the uroxanic acid was precipitated by hydrochloric acid.

Analyses of the acid and its salts led to the formula $C^4H^4N^2O^6$, whereas Städeler found $C^4H^4N^2O^6$. From Strecker's formula it appears that uroxanic acid is formed from uric acid by oxidation and addition of water:

Potassium Uroxanate, $C^4H^4K^2N^2O^6 + 3H^2O$, or $3\frac{1}{2}H^2O$, does not give off all its water of crystallisation till it begins to decompose. The **silver salt**, $C^4H^4Ag^2N^2O^6$, obtained from it by precipitation, is a white crystalline powder. The **barium salt**, $C^4H^4Ba^2N^2O^6 + 5H^2O$, prepared in like manner, gives off its water at 100°-110°. The **calcium salt**, $C^4H^4Ca^2N^2O^6 + 4H^2O$, similarly prepared, dissolves in hot water and separates, on addition of alcohol, in white needle-shaped crystals.

USNIC ACID, $C^8H^{10}O^7$ (Stanhouse, *Proc. Roy. Soc.* xviii. 222). **Preparation from *Usnea barbata*.**—This lichen is macerated with a dilute solution of sodium carbonate, and the crude dark green acid, precipitated from the turbid solution by hydrochloric acid, is mixed with milk of lime and warm water at 40°. From the clear lemon-yellow filtrate the usnic acid is precipitated by hydrochloric acid in pale yellow flocks.

Sodium usnate forms pale yellow silky needles, not very soluble in cold water, more soluble in alcohol; it is easily decomposed by carbonic acid. The **calcium salt**, which separates from a boiling solution, is also completely decomposed by carbonic acid.

Usnic acid, identical with that from *Usnea barbata*, is likewise obtained from *Xeraria prunastri*, in which it exists together with evernic acid (p. 496). The two acids extracted from the lichen by milk of lime are precipitated together by hydrochloric acid, and the dried precipitate is treated with boiling alcohol, which dissolves the evernic acid, and leaves the usnic acid, which may be purified as above.

Usnic acid is isomeric with cladonic (β -usnic) acid (p. 353). The two acids are distinguished by their melting points, usnic acid melting at 202°, cladonic acid at 176°. Moreover cladonic acid, when subjected to dry distillation, yields β -orcin (iv. 204), whereas pure usnic acid yields none.

V

VACCINIUM. The fruit of the red whortleberry (*Vaccinium Vitis Idæa*) has been examined by Gräger (*N. Jahrb. Pharm.* xxxvi. 208) according to the method for the examination of fruits given by Fresenius (ii. 712, 716). The juice obtained from the crushed perfectly ripe berries, by four times repeated exhaustion with distilled water, was found to contain:

Free acid, reckoned as malic (better, however, as citric acid)	1.97	Potash	0.06
Fruit-sugar	5.18	Lime	0.13
Tannic acid	0.48	Magnesia	0.01
Proteids (pectin-substances), sus- pended fat, &c.	2.33	Ferric oxide	0.02
		Water	89.81

The berries yielded 10.18 p.c. soluble substances, 85.61 p.c. water, and 4.20 p.c. residue, dried at 100°, which contained 0.1 p.c. ash. The free acid is chiefly citric, with a little malic acid. The proportion of ferric oxide is unusually large. For concentrating the juice Gräger recommends the addition of 5 or 6 grams of sodium bicarbonate to 0.5 kilos. of whortleberries.

Vaccinin.—This name is given by E. Claassen (*Arch. Pharm.* [2], cxlvii. 248) to a slightly bitter inodorous non-nitrogenous substance which he obtained from the whortleberries by boiling the fresh plants in water with a little milk of lime, &c. It crystallises in long colourless silky needles, melts when heated, is not precipitated from its solutions by basic lead acetate or tannic acid.

VALERAL or **VALERIC ALDEHYDE**, $C^5H^{10}O$. 1. **Normal Valeral**, $CH^3-(CH^2)^4-CHO$, prepared from normal valeric acid by distilling the calcium salt with an equivalent quantity of calcium formate, and purified by fractional distillation, boils at 102° , dissolves completely in a large quantity of water, and forms a crystalline compound with sodium bisulphite (Lieben & Rossi).

2. **Isovaleral. Ordinary Valeric Aldehyde**, $\begin{matrix} H^1C \\ H^2C \end{matrix} > CH-CH^2-CHO$ (A. Schröder,

Deut. Chem. Ges. Ber. iv. 400, 468). This compound boils at 92.5° under a barometric pressure of 758.2 mm. Sp. gr. = 0.768 at 12.5° . Vapour-density = 43.06 ($H = 1$; calc. = 43).

Valeral-ammonium, $C^5H^9(NH^4)O$, exhibits the normal vapour-density. A determination at 160° gave the value 52.16; calc. 51.5° . ($H = 1$). The vapour-density of the hydrated compound, $C^5H^9(NH^4)0.7H^2O$, is by experiment 14.31, which is also normal; for the 7 mols. of water occupy 14 volumes, and if the group $C^5H^9(NH^4)O$ occupies two volumes, the hydrated molecule should occupy 16 volumes, and the molecular weight 220, divided by 16, gives 14.5, which is nearly the same as 14.31.

Action of Chlorine on Valeral.—When chlorine is passed into valeral, first in the cold, afterwards at 145° , as long as it is absorbed, the compound $C^5H^9Cl^2O$ is formed according to the equation:

This body, which may be regarded as a derivative of the condensation-product, $C^5H^{10}O$ (p. 1196), is a liquid having a fetid odour like that of the goat, and boiling at $203^\circ-204^\circ$. It does not combine with alkaline bisulphites, and is not acted upon by cold nitric acid. Boiled with fuming nitric acid it yields a nitro-derivative. On treating it with a boiling solution of caustic soda in alcohol, 2 mols. of hydrochloric acid are taken out, and the body $C^5H^9Cl^2O$ is obtained, which is an oily liquid having a pleasant smell of mint, and boiling at $208^\circ-210^\circ$.

Chlorovaleral, C^5H^9ClO , is formed, together with more highly chlorinated products, when valeral is imperfectly saturated with chlorine in the cold. It is a liquid boiling at $134^\circ-135^\circ$, and forming crystalline compounds with alkaline bisulphites.

Thiovaleral, C^5H^9S .—Dry hydrogen sulphide does not act upon valeral, but when this gas is passed into its aqueous solution, white crystals separate, consisting of thiovaleral. This compound is insoluble in water, soluble in alcohol and ether, and separates from a hot ethereal solution in asbestos-like crystals. It has a most offensive and persistent odour, melts at 69° , and, when heated very strongly, decomposes, giving off white fumes having an indescribable smell; but it may be sublimed without decomposition in a vacuum. Vapour-density, obs. = 50.76; calc. = 61.

Valeraldine, C^5H^9NS (v. 974), is formed by passing dry ammonia over thiovaleral:

Thus prepared it contains an excess of ammonia, which may be removed by a current of hydrogen, or by dissolving it in ether and evaporating the solution in a vacuum over sulphuric acid. It is thus obtained as an oil, which, by standing over sulphuric acid in a vacuum for some time, and being then exposed for a short time to the air, becomes crystalline. The oily valeraldine may also be solidified by passing hydrocyanic acid over it. It melts at 41° , and is a very indifferent body, not being acted upon by hydrocyanic acid, cyanogen gas, or cyanogen chloride; it is insoluble in water, soluble in alcohol or ether; from the latter it crystallises in white fern-like leaves, having the consistence of wax. Its odour resembles that of acetamida. When heated, it distils with decomposition; but in a vacuum it sublimes undecomposed.

Seleniovaleral, C^5H^9Se , obtained by passing hydrogen selenide into the aqueous solution of valeral, is a crystalline solid, which cannot be re-crystallised, as its solution in ether, alcohol, or methyl-alcohol soon decomposes, with separation of selenium in the form of a mirror; but it may be purified, as it volatilises in a current of gas with aqueous vapour at the common temperature. It forms white crystalline crusts, melting at 56.5° ; its odour is exceedingly offensive, and produces difficulty of respiration and palpitation of the heart. It decomposes at 30° in contact with mercury. With dry ammonia it forms seleniovaleraldine, a compound closely resembling valeraldine (Schröder).

Carbovaleraldine, $C^5H^9N^2S$, is formed either by shaking a mixture of carbon

formed from the iodopropionic acid in question is not normal valeric or propyl-acetic acid, but methyl-ethyl-acetic acid. Respecting *trimethyl-acetic acid*, see p. 1182.

Normal Valeric, Propyl-acetic, or Butyl-formic Acid, $\text{CH}_3(\text{CH}_2)_3\text{COOH}$ (Lieben & Rossi, *Gazzetta chimica italiana*, i. 239). This acid is formed by oxidation of normal amyl alcohol, and by distilling normal butyl cyanide with alcoholic potash in a retort with reversed condenser as long as ammonia continues to escape. On distilling off the alcohol (which contains ammonia and a mixture of mono-, di-, and tri-butylamine, formed as secondary products), dissolving the residual saline mass in water, saturating approximately with sulphuric acid, filtering to separate potassium sulphate, evaporating the filtrate to dryness, and treating the residue with dilute sulphuric acid, the valeric acid is separated and rises as an oil to the surface. This oily liquid washed with a little water and distilled, rejecting the first few drops, which are slightly humid, yields pure valeric acid boiling within an interval of 1.5° , and yielding by analysis 58.63 p.c. C., and 9.62 H., the formula $\text{C}_5\text{H}_{10}\text{O}_2$ requiring 58.82 C., and 9.80 H.

Normal valeric acid has an odour more like that of pure butyric acid than that of ordinary valeric acid. It boils at $184^\circ\text{--}185^\circ$ (corr.) under a pressure of 736 mm. When cooled to -16° , it becomes slightly viscous, but does not solidify. A cubic centimeter of this acid dissolves at 16° about 1 c.c. of water; on adding more water, a lower aqueous layer is formed, on which the valeric acid floats, but after the addition of 27 c.c. water to 1 c.c. acid, complete solution takes place. The specific gravity of normal valeric acid referred to water at the same temperature is as follows:—

Temperature	0°	20°	40°	99.3°
Specific gravity	0.9577	0.9415	0.9284	0.9034

Normal Valerates.—All the following salts were prepared by saturation, excepting the copper salt, which being but sparingly soluble, was obtained by precipitation. The *sodium salt* is very soluble in water, and the hot solution gelatinizes on cooling. The *barium salt*, $(\text{C}_5\text{H}_9\text{O}_2)_2\text{Ba}$, is more soluble in hot than in cold water, and its hot saturation solidifies on cooling to a mass of unctuous laminar crystals. The dry salt, obtained by evaporating the solution at ordinary temperatures and exposing the crystals to the air, is neutral and anhydrous. 100 pts. of a solution saturated at 10° contain 16.906 pts. of the anhydrous salt. The *calcium salt* is obtained by evaporation at ordinary temperatures in small, shining, unctuous laminae, resembling those of the barium salt; they contain $(\text{C}_5\text{H}_9\text{O}_2)_2\text{Ca} + \text{H}_2\text{O}$, and give off their water of crystallisation at 100° . This salt exhibits a maximum of solubility at about 70° , so that it separates from a hot saturated solution on cooling, and from a cold saturated solution on heating. A solution saturated at about 20° contains 8.0809 p.c. of the anhydrous salt. The *manganous salt*, $(\text{C}_5\text{H}_9\text{O}_2)_2\text{Mn} + \text{H}_2\text{O}$, forms small faintly rose-coloured crystals, which give off their water at 100° . It is much more soluble in cold than in hot water, and a solution saturated in the cold deposits, when heated, a precipitate (probably of basic salt) which does not redissolve completely on cooling; this decomposition by heat takes place with especial facility in dilute solutions, so that such solutions cannot be concentrated by heat.

The *cupric salt*, $(\text{C}_5\text{H}_9\text{O}_2)_2\text{Cu}$, is obtained, by precipitating the sodium salt with cupric sulphate, as an azure-green substance, which partly dissolves when washed and digested with water at ordinary temperatures. The resulting sky-blue solution, when evaporated in a vacuum over sulphuric acid, yields the neutral salt in groups of green microscopic needles; its powder has a lighter colour inclining to sky-blue. This salt is likewise more soluble in cold than in hot water, its solution becoming turbid when heated, and always depositing a small quantity of basic salt, which does not redissolve on cooling; and on evaporating the solution by heat, a residue is obtained consisting chiefly of a sky-blue basic salt. On boiling a dilute solution of the neutral salt, or heating a solution of the basic salt, cupric oxide is precipitated, and valeric acid volatilises with the aqueous vapour. The same decomposition appears also to take place partially at ordinary temperatures. The *zinc salt*, $(\text{C}_5\text{H}_9\text{O}_2)_2\text{Zn}$, forms thin, shining, transparent laminae, unctuous to the touch. 100 pts. of a solution, saturated at $24\text{--}26^\circ$, contain 2.64 pts. of the salt; the solution becomes turbid when heated, but the precipitate redissolves on cooling.

Isovaleric, Isopropyl-acetic, or Isobutyl-formic Acid, $(\text{CH}_3)_2\text{CH}\cdot\text{CH}_2\cdot\text{COOH}$. **Ordinary Valeric Acid.**—The properties of this acid and its salts, as obtained from various sources, have been carefully studied by Erlenmeyer & Hell (*Ann. Ch. Pharm.* clx. 267).

1. **Valeric Acid, prepared by boiling Isobutyl Cyanide with Alcoholic Potash.**—The acid thus prepared is a colourless, oily, optically inactive liquid, which makes a white spot on the tongue. The *silver salt* crystallises from neutral solutions in dendritic bundles,

from solutions containing a little free acid, especially acetic acid, in large, highly lustrous, apparently triclinic laminae. It is sparingly soluble in cold water, more soluble in hot water, and in water containing free fatty acids. It is permanent in the air, and not much altered by light. The crystals rotate rapidly on dilute nitric acid. The barium salt crystallises in anhydrous prisms or laminae belonging to the triclinic system; they are permanent in the air, and rotate quickly on water. The aqueous solution decomposes gradually at ordinary temperatures, more quickly on boiling, giving off valeric acid.

2. From *Valerian root*.—The crude acid contained formic acid, acetic acid, and an acid boiling at 180°–195°, but not butyric acid; it was dextrogyrate, but by recrystallisation of the barium salt, a perfectly inactive acid was obtained. The silver and barium salts resemble those of the acid from isobutyl cyanide.

3. From *Amyl Alcohol*.—The separation of the active and inactive amyl alcohols was effected by Pasteur's method, depending on the difference of solubility of the corresponding amylsulphates of barium (i. 203). The valeric acid prepared from the inactive alcohol, when purified by recrystallisation of its barium salt, and separation therefrom, was absolutely destitute of rotatory power, and agreed in other respects with the acids prepared from isobutyl cyanide and from valerian root. The valeric acid prepared from the active amyl alcohol (too small in quantity for complete purification) boiled for the most part between 168° and 171°. Rotatory power = +30° to 40°. The silver salt crystallises from acid solution in laminae, from neutral solution in felted feathery crystals. The barium salt remains on evaporation as a thick syrup which often only after some months deposits small crystals resembling those of the barium salt above described. The syrupy mother-liquor scarcely wets paper, so that the crystals cannot be freed from it either by absorption or by pressure; it dries up to a varnish. The solution of the salt dialyses with peculiar facility through parchment paper. The salt dissolves in all proportions in alcohol, but is insoluble in ether.

The separation of active valeric acid from a mixture of the two cannot be completely effected by crystallisation of their barium salts, or by fractional distillation, or by partial oxidation of a mixture of the two alcohols. Erlenmeyer & Hell found, however, in a commercial product consisting of a mixture of amyl valerate and amyl alcohol (residues of the preparation of valeric acid) a material for the preparation of very active valeric acid. The acid obtained from it by saponification of the valeric ether had a rotatory power = +48.7°, and boiled at 172.5°–173.5° under a pressure of 721 mm.

Valeric acid, active or inactive, is easily oxidised by a mixture of 2 mols. water, 1 mol. strong sulphuric acid, and as much potassium dichromate as can dissolve therein at 20°. The products are acetic acid, carbon dioxide, and water. If the inactive acid were isobutyl-formic acid, its oxidation would probably take place according to the equation:

yielding 123.9 p.c. CO₂. The acid from inactive amyl alcohol actually yielded 120.04, and that from valerian root 123.4 p.c. CO₂. The quantity of carbonic acid produced by oxidation of the active acid was too variable to give any distinct indication of its constitution.

The active acid, heated for a quarter of an hour with a few drops of strong sulphuric acid, becomes optically inactive without alteration of its other properties.

4. From *Leucine*.—The cold saturated solution of leucine, prepared by boiling elastic tissue or various proteids with dilute sulphuric acid, is optically inactive. The valeric acid obtained by heating it with a mixture of potassium dichromate or manganese dioxide and sulphuric acid, or by fusing it with potash, was too small in quantity to be completely purified; it contained a little acetic acid. Its rotatory power was +17°. The barium salt showed little tendency to crystallise, and it was impossible to decide whether it consisted of a single salt or of a mixture of two.

Erlenmeyer & Hell are of opinion that valeric acid obtained from valerian root, or by oxidation of amyl alcohol, or of leucine from various proteids, is almost always a mixture in various proportions of two acids, one of which is inactive isobutyl-formic acid, while the other is the optically active acid, whose barium salt is more soluble and less easily crystallisable than that of the inactive acid.

The following table exhibits a comparative view of the properties of the valeric acids from the four sources above mentioned. The specific gravity in each case is referred to water at the same temperature. The optical rotation is given for a column 50 cm. thick, in degrees or divisions of a Ventke's saccharimeter. The properties of normal valeric acid, as determined by Lieben & Rosol, are also given for comparison.

VALERIC ACID.

According to Pierre a. Puchot (*Compt. rend.* lxxv. 1005) valeric acid obtained by oxidation of ordinary amyl alcohol, boils at 178° under a pressure of 760 mm. and exhibits the following specific gravities:

Sp. gr.	0.9470	0.8972	0.8542	0.8095
at	0°	54.65°	99.9°	147.5°

A mixture of the concentrated acid with water boils regularly between 99.8° and 100° , giving off vapours which condense to two layers, the upper of which is the pure acid, and the lower its aqueous solution.

Ordinary calcium valerate separates from its solution at ordinary temperatures in crystals containing 3 mols. water (Barone, *Deut. Chem. Ges. Ber.* iv. 758).

Zinc valerate unites with ammonia, forming the compound $(C^4H^9O^2)_2Zn.2NH^3$ (*Monatsh.* lxx. v. 30).

VALERATES. Pierre a. Puchot (*Ann. Chim. Phys.* [4], xx. 234) have determined the boiling points and densities of the ordinary valerates of methyl, ethyl, and butyl (from fermentation butyl alcohol), with the following results:

	Methyl Valerate, $C^4H^9O^2.CH^3$	Ethyl Valerate, $C^4H^9O^2.C^2H^5$	Isobutyl Valerate, $C^4H^9O^2.C^4H^9$
Boiling point	117.25° at 755 mm.	135.5° at 760 mm.	173.4° at 760 mm.
Specific gravity at	$0^{\circ} = 0.9005$	$0^{\circ} = 0.886$	$0^{\circ} = 0.8884$
	$41.5^{\circ} = 0.8581$	$55.7^{\circ} = 0.832$	$49.7^{\circ} = 0.8438$
	$64.3^{\circ} = 0.8343$	$99.63^{\circ} = 0.7843$	$100^{\circ} = 0.7966$
	$100.1^{\circ} = 0.7945$	$122.5^{\circ} = 0.7582$	$155.8^{\circ} = 0.7428$
Odour	like bananas	like rennet apples and <i>Mentha aquatica</i> ; excites coughing	like the ethylic ether

VALERIDINE, $C^6H^{10}N$, and **VALERITRINE**, $C^{10}H^{17}N$. Two volatile bases obtained by the action of alcoholic ammonia on valeral at 150° . Their formation takes place in the manner shown by the following equations:

Valeridine hydrochloride crystallises in laminae; valeritrine forms a characteristic picrate (Ljubarin, *Deut. Chem. Ges. Ber.* iv. 976; v. 1101).

VALERONITRIL, C^4H^5N , is formed, together with valeramide, by heating valeric acid with potassium sulphocyanate. It boils at 125° – 128° . Fuming nitric acid converts it into a crystalline compound not yet examined (Letts, *Deut. Chem. Ges. Ber.* v. 669).

VANADIUM. This element has been found in trap-rocks by R. Apjohn (*Chem. Soc. J.* [2], x. 1116), and in iron ores from the county of Antrim in Ireland, by R. J. Hodges (*Chem. News*, xxvi. 238).

Vanadates. *Eosite.*—This name is given by A. Schrauf (*Jahrb. f. Mineralogie*, 1871, 163, 451) to a quadratic, aurora-red mineral implanted on cerussite at Lead-hills, and regarded as a species intermediate between molybdate and vanadate of lead. The crystals exhibit the forms OP and P, the latter = 62.50° . Streak brownish-yellow. Hardness = 3.

Vanadinite, $3(VO^4)Pb^2.PbCl^2$.—On the artificial formation of this mineral, see 1st Suppl. 1125.

Maskelyne a. Flight (*Chem. Soc. J.* [2], x. 1053) found in a vanadinite from South Africa (sp. gr. 6.61):

Pb.	VO	Cl
78.416	19.829	2.56
77.770	18.670	undetermined

The absence of Mo, Cr, and P was directly established.

The relations between vanadinite, descloisite, and dechenite have been examined by A. Schrauf (*Jahrb. f. Mineralogie*, 1871, 638; *Chem. Soc. J.* [2], ix. 400). Of the two varieties of vanadinite from Bannal, the darker is identical with descloisite from Peru, while the lighter is nearly related crystallographically to descloisite, obviously to the dechenite of Niederschleissbach.

Vanadiolite.—A mixture of calcic hypovanadate with augitic substance, found, together with lawrowite, near Lake Baikal (see LAWROWITZ, p. 726).

VANILLIC ACID or **VANILLIN**, $C^8H^8O^3$. The odorous principle of vanilla, the fruit of *Vanilla planifolia*, has been the subject of various contradictory statements. Gobley assigned to it the formula $C^{10}H^{10}O^3$; Stokkebye regarded it as $C^{10}H^{10}O^{13}$ (v. 994). W. v. Leutner (*Russ. Zeitschr. Pharm.* x. 641, 676, 706; *Jahresh. f. Chem.* 1871, 816) regards it as a neutral substance, *vanillin*, having the composition $C^8H^{10}O^3$, and states that when boiled with potash-ley it takes up water and is converted into a monobasic acid, *vanillic acid*, $C^8H^{10}O^4$, the silver salt of which contains $C^8H^{13}AgO^4$.

The true composition of vanillic acid has been determined by P. Carles (*Bull. Soc. Chim.* [2], xvii. 12), who has described and analysed many of its derivatives. The vanillic acid, which forms an efflorescence on the surface of the ripe fruit, and is at the bottom of the vessels in which they are kept, was dissolved in water, decolourised by animal charcoal, and several times recrystallised. By slow cooling it separates in large translucent prisms, which may attain a length of more than 2 cm. It has a pungent taste, and when fresh and pure, only a faint aromatic odour, which, however, becomes stronger on warming. It melts between 80° and 90° , and may be sublimed, but when distilled from a tube, passes over with distillation at 280° , and becomes partially resinised. It is very soluble at ordinary temperatures in alcohol, ether, chloroform, carbon sulphide, and oils, gives off 1.2 p.c. water at 15° , and a very large quantity at boiling heat. It decomposes carbonates and saturates alkaline bases completely at ordinary, and alkaline earths at higher temperatures. Its *lead*, *magnesium*, and *zinc salts*, $(C^8H^9O^4)^2M$, are sparingly soluble in water, and are obtained by precipitation. The lead salt is decomposed by boiling water into a more soluble acid salt and resinous basic salts. These salts are but little altered by exposure to the air, but the ammonium, potassium, sodium, barium, and calcium salts quickly turn brown in contact with the air, and leave a blackish indistinctly crystalline residue when their solutions are left to evaporate in a vacuum.

Bromovanillic acid, $C^8H^7BrO^4$, is formed by adding bromine in slight excess to a concentrated lukewarm aqueous solution of vanillic acid—taking care to prevent rise of temperature—as a precipitate which, after crystallisation from alcohol, and finally from boiling water, with addition of animal charcoal, forms nacreous, scentless, light yellow crystals, which dissolve sparingly in cold water, more easily in alcohol, ether, and chloroform, melt at 161° , and sublime without decomposition. The mother-liquor contains more highly brominated products.

Mono-iodovanillic acid, $C^8H^7IO^4$, obtained by adding alcoholic iodine to aqueous vanillic acid, forms white nacreous crystals which, after two recrystallisations from alcohol, melt at 174° , sublime undecomposed, and have a faint odour. *Di-iodovanillic acid*, $C^8H^6I_2O^4$, obtained by using an excess of iodine, forms nacreous crystals slightly soluble in boiling water, insoluble in cold chloroform, soluble in warm alcohol and ether.

With *chlorine*, vanillic acid does not form any crystallised substitution-products.

Action of melting Potash on Vanillic acid.—When vanillic acid is gradually added to melting potash, the cooled mass treated with strong hydrochloric acid, the whole then shaken with ether, and the ethereal solution left to evaporate, small warty crystals are obtained of a compound regarded by Carles as oxyvanillic acid. This substance, after two crystallisations from boiling water, forms white, scentless, prismatic crystals melting at 169° , slightly soluble in cold, very soluble in boiling water, soluble in alcohol and in ether. It saturates bases completely, and some of its salts are crystalline. Its solution does not alter the colour of pure ferrous salts, but in presence of traces of ferric oxide, a very deep green colour is produced, which is destroyed by nitric acid, chlorine, and sulphurous acid.

Action of Hydriodic acid.—Vanillic acid, heated to 100° in a sealed tube for 30 hours with five times its weight of fuming hydriodic acid, forms a brown product which, on distillation, yields methyl iodide (Carles).

Formation of Vanillic acid from Conifera.—When coniferin, $C^{14}H^{22}O^4$, the glucoside contained in the cambium of coniferous woods (*1st Suppl.* 480), is digested at 26° – 36° with water and a small quantity of emulsin, it splits up into glucose and a substance which separates in white crystalline floccs, and, after purification by solution in ether, has the composition $C^8H^{10}O^4$. This substance acquires the odour of vanilla on exposure to the air, and when it is oxidised with chromic acid mixture, the product on shaken with ether, and the ether left to evaporate, there remains an oil which, on cooling, solidifies to a substance identical in composition, melting point, and all its

other properties, with vanillic acid from vanilla, forming the same salts, and the same bromine- and iodine-derivatives (Tieman & Haarmann, *Deut. Chem. Ges. Ber.* vii. 608).

When coniferin, the crystalline substance $C^{10}H^{10}O^8$, or vanillic acid, is fused with potash, protocatechuic acid is formed, and vanillic acid heated with hydriodic acid yields methyl iodide. Hence vanillic acid may be inferred to be a methylic ether of

protocatechuic aldehyde, viz. $C^8H^8 \begin{pmatrix} OCH^3 \\ OH \\ COH \end{pmatrix}$. This aldehyde has not been actually

separated from the products of the action of hydriodic acid on vanillic acid, but it is formed, together with methyl chloride, when vanillic acid is heated to 180° – 200° with dilute hydrochloric acid. With *acetic anhydride* vanillin yields acetyl-vanillic

acid, $C^8H^8 \begin{pmatrix} OCH^3 \\ OC^2H^3O \\ COH \end{pmatrix}$, and with *benzoyl chloride* it yields benzoyl-vanillic

acid, $C^8H^8 \begin{pmatrix} OCH^3 \\ OC^7H^7O \\ COH \end{pmatrix}$.

The substance $C^{10}H^{10}O^8$ is probably a methyl-ethylic ether of protocatechuic aldehyde, or an ethylic ether of vanillic acid, and may be represented by the formula

$C^8H^8 \begin{pmatrix} OCH^3 \\ OC^2H^3 \\ COH \end{pmatrix}$, this view being confirmed by the fact that hydriodic acid decomposes

the substance, with formation of methyl iodide and ethyl iodide. Protocatechuic aldehyde was not actually detected among the products, but protocatechuic acid and pyrocatechin were found (Tiemann & Haarmann).

VETCH. *Vicia sativa*.—The composition of three varieties of vetch-seed has been determined by H. Weiske-Proskau (*Ann. d. Landwirthschaft. Wochenblatt*, Sept. 6, 1871; *Chem. Soc. J.* [2], x. 840).

On the formation of Asparagin in vetches, see p. 108.

VINYL-COMPOUNDS (E. Baumann, *Ann. Ch. Pharm.* clxiii. 308). The *bromide* and *iodide* of vinyl, C^2H^3Br , and C^2H^3I , are acted on by *sodium methylate* at ordinary temperatures, even in the shade, yielding the same products as when the action takes place at a higher temperature, viz. acetylene, sodium bromide, methyl alcohol, and a trace of a substance which may perhaps be allyl alcohol, as it gives rise to an odour exactly resembling that of acrolein when treated with dilute sulphuric acid and potassium dichromate.

Pure *potassium cyanide* (prepared by saturating alcoholic potash with gaseous hydrocyanic acid) and *silver cyanide*, have practically no action on vinyl bromide, even after several hours' heating at 140° – 150° .

When vinyl bromide is kept in a sealed tube in the dark, no change ensues, even after several weeks; but if exposed to direct sunlight, it becomes changed into an isomeric, solid, non-crystalline, porcelain-like, elastic substance; this change takes place more rapidly with moist bromide than with the perfectly dry substance; the presence of a small quantity of alcohol neither accelerates nor retards the change. This solid substance has the sp. gr. 2.075, whereas the liquid bromide has the sp. gr. 1.62 (Regnault). It begins to decompose at 125° – 130° , and is but little acted on by boiling alcoholic potash; after twelve hours heating to 180° – 200° , with this reagent, however, it forms a brown-black substance, insoluble in all menstrua, all the bromine being removed from it without evolution of gas. Sulphuric acid carbonises the substance on being heated with it; boiling nitric acid has but little action on it; bromine dissolves it, forming a loose compound, which splits up into bromine and the original substance, on treatment with water, alcohol, or alkalis.

Vinyl chloride undergoes a change by the action of sunlight, producing an isomeride of similar appearance and properties to the above-described substance. The specific gravity of the solid modification is 1.466; it can be heated to 120° without decomposition, but melts to a black-brown mass at a higher temperature, it is not dissolved by bromine.

Dichlorethylidene (chlorinated vinyl chloride), boiling at 86° , is also changed into a solid isomeride by the action of light. This body has been described by Regnault, and a similar modification of brominated vinyl bromide by Sawitsch.

The preparation of vinyl iodide from ethylene iodide is difficult, the yield being very small; it is not obtained by the action of potassium iodide on vinyl bromide; sunlight decomposes it, setting free iodine, which probably prevents the isomeric transformation of the unaltered iodide, as a trace of free iodine prevents this change in the case of vinyl bromide.

VIRIDINE, $C^{12}H^{10}N$. On the occurrence of this base in tobacco-smoke, *see* TOBACCO (p. 1161).

VIVIANITE, $3FeO.P^{20}_2 + 8H^2O$, or $Fe^3(PO^4)^2 + 8H^2O$. Maskelyne & Flight (*Chem. Soc. J.* [2], ix. 6) have analysed several specimens of vivianite from Cornwall.

a. Pale blue-green crystals (examined crystallographically by G. vom Rath, *Pogg. Ann.* cxxvi. 405), occurring with quartz, and chalybite in the cavities of a gangue composed of blende, with small quantities of galena, iron pyrites, copper pyrites and mispickel. *b.* From the same locality; dark blue fragments of pulverulent structure, sometimes enclosing imperfect dark brown crystals. *c.* and *d.* Fine crystals from Fernando Po.

	FeO	FeO ^a	P ²⁰ O ^a	CO ^a	SiO ^a	H ² O	Organic matter	
<i>a.</i>	42.71	1.13	28.53	—	—	28.98	—	101.33
<i>b.</i>	37.21	9.17	23.90	5.16	0.81	23.87	0.29	100.41
<i>c.</i>	42.89	0.80	28.79	—	—	29.44	—	101.92
<i>d.</i>	38.50	5.08	27.80	—	—	28.33	—	99.71

The whole of the iron was doubtless originally present as monoxide; but the nearly colourless powder of the variety *a* oxidises even during trituration, its colour changing to deep blue. Bearing this in mind, the composition of all the species may be represented by the ordinary formula of vivianite.

VOLCANIC EMANATIONS. On the Gases evolved from the Fumaroles of Vesuvius and Etna, *see* Scacchi (*Min. Mitth.* 1871, 54; *Jahresb. f. Chem.* 1871, 1220; 1872, 1175).

On the Gaseous Exhalations from the Solfataras of Pozzuoli: S. de Luca (*Ann. Chim. Phys.* [4], xxvi. 289; *Jahresb.* 1872, 1175; *Chem. Soc. J.* [2], x. 294). *See* further the article GASES, VOLCANIC, in this volume (p. 550).

W

WAD. C. P. Williams (*Chem. News*, xxi. 237) describes an anhydrous wad occurring in the quartz-veins of the gold districts of Nueva Providencia, Venezuela, containing: 46.973 p.c. MnO, 7.645 O, 4.073 Fe²O³, 15.934 Al²O³, 0.528 CuO, 3.555 CoO, 10.885 NiO, trace of ZnO, 1.605 CaO, 1.653 MgO, and 8.653 SiO².

Analysis of three specimens of wad from different localities in Germany are given by H. Ludwig (*Arch. Pharm.* [2], cxliii. 101; *Jahresb.* 1871, 1284).

WALNUT. *See* RESININ (p. 1039).

WATER. On the Compressibility of Water, *see* LIQUIDS (p. 756).

Specific Heat.—G. A. Hirn finds that the specific heat of water does not exhibit any irregularity near its point of maximum density, but merely changes somewhat more quickly below than above that point (*Compt. rend.* lxx. 831).

Freezing.—Boussingault (*Compt. rend.* lxxiii. 77) observed that water enclosed at 4° in a cast-steel tube, thick enough to be regarded as inextensible, remained liquid for several days at -24° , as was shown by the mobility of a steel ball enclosed within the tube. Solidification took place as soon as the tube was opened and the water allowed to expand.

Martins & Chancel (*Ann. Chim. Phys.* [4], xxvi. 560) have examined the physical phenomena attending the bursting of shells by the freezing of water. However low the temperature of the air might be, that of the enclosed water, at the moment of splitting of the shell, which took place without any scattering of fragments, never sank below -4.2° . The proportion of water frozen varied from 20 to 30 p.c., and

the pressure thereby exerted was sufficient to reduce the entire volume by $\frac{1}{15}$ to $\frac{1}{10}$ (compare iii. 79).

According to Tellier (*Compt. rend.* lxxv. 506), ordinary water can be cooled in a glass vessel to -3° or -4° without freezing, even when briskly shaken. A very violent concussion, however, frequently causes it to freeze, and the solidification may be instantly determined by dropping in a crystal of ice, needless of ice being then formed, which traverse the entire mass, and the temperature rising to 0° . Those phenomena are similar to those which take place in supersaturated saline solutions.

Zöppritz (*Pogg. Ann. Ergänz.* v. 497) has shown by careful experiments that sea-water in freezing exhibits no deviation from the general law which governs the variation of density with temperature in all liquids excepting pure water.

Bolley (*Dingl. pol. J.* cxviii. 267) has shown that the concentration which is observed in sea-water and in strong saline solutions in general by the act of freezing, takes place also in spring and river-waters, even in such as have but a very slight degree of hardness. A litre of filtered water from the Lake of Zürich left on evaporation 0.128 gram of saline residue (dried at 110°), whereas a litre of filtered water from the thawed ice of the same lake yielded only 0.026 gram.

Decomposition.—On the decomposition of water by zinc in conjunction with a more negative metal, see ELECTROLYSIS (p. 454).

H. T. Brown (*Chem. Soc. J.* [2], x. 577) finds that water is decomposed during vinous fermentation, and that the decomposition is facilitated by an increase of atmospheric pressure.

According to V. Meyer (*Compt. rend.* lxxiv. 195), vapour of water passed over boiling sulphur is decomposed, with formation of sulphurous and thiosulphuric acids.

Detection and Estimation.—For the detection of water in the state of vapour Schorras (*Deut. Chem. Ges. Ber.* iii. 11) recommends paper impregnated with solution of calcium platinocyanide, and decolorised by heating. Exposure to vapour of water immediately restores the colour.

The presence of water in common Ether may be detected by dropping the ether into carbon sulphide previously purified by means of silver amalgam. The slightest quantity of water produces a milky turbidity (V. Wartha, *Deut. Chem. Ges. Ber.* iii. 82).

Water may be detected in Essential Oils by the turbidity which it produces when the oil is mixed with several times its volume of petroleum ether (Louché, *J. p. Chem.* [2], vi. 159).

On the estimation of water in Acetic acid by observation of the freezing temperature of the aqueous acid, see ACETIC ACID (p. 5).

On the mode of combination of Water of Crystallisation, see F. v. Kobell (*Pogg. Ann.* cxli. 446; *Jahresb. f. Chem.* 1870, 204).

F. Mohr infers from Landolt's tables of the boiling points, specific gravities, and refractive indices of isomeric bodies, that when hydrogen is present in a compound in the form of water, it lowers the index of refraction, but raises the specific gravity and the boiling point (*Deut. Chem. Ges. Ber.* iv. 156).

Water Analysis. Estimation of free Oxygen.—Schützenberger a. Gérardin (*Compt. rend.* lxxv. 879) estimate the free oxygen in water by means of sodium hyposulphite, NaHSO_3 (Schützenberger's hydrosulphite, 1st *Suppl.* 1063), which absorbs oxygen with great rapidity. The reaction consists in the conversion of the hyposulphite into the acid sulphite of sodium, and the amount of hyposulphite thus oxidised by a water is determined by means of Couper's soluble aniline-blue, which is instantly decolorised by the hyposulphite, and not affected by the acid sulphite. Sodium hyposulphite also decolorises an ammoniacal solution of cupric oxide, while the sodium sulphites do not, and this solution may also be used as a means of titrating the test-solution of hyposulphite. It is necessary to exclude the air from the water during its treatment with the hyposulphite, and for this purpose it is covered with a thin layer of oil, beneath which the beak of the burette is made to dip. The hyposulphite solution is added from a burette, first to the standard solution of copper to determine its strength, and then to a litre of the water coloured with Couper's blue. The disappearance of the colour in each case shows the presence of anoxidised hyposulphite, and therefore the completion of the action.

A method of detecting air dissolved in water is described by A. Andersen (*Pogg. Ann.* cxliii. 142; *Jahresb. f. Chem.* 1871, 205).

On the estimation of Carbonic acid in Sea-water, see p. 261 of this volume; in Chloraous Spring-water; K. Knapp (*Ann. Ch. Pharm.* cxviii. 112; *Chem. Soc. J.* [2], ix. 422).

On the estimation of *Sulphuric acid* in water, see A. Müller (*Deut. Chem. Ges. Ber.* iii. 881; *Chem. Soc. J.* [2], ix. 439).

On the detection and estimation of *Nitrous* and *Nitric acid* in Waters, see pp. 854, 858. On the estimation of *Nitric acid*, see also Wittstein (*Dingl. pol. J.* cc. 123; *Chem. Soc. J.* [2], ix. 754). E. Nicholson (*Chem. News*. xxvi. 89); F. Schulze (*Zeitschr. anal. Chem.* 1872, 313; *Jahresb.* 1872, 881).

On the estimation of *Nitrates* in Well Water: J. M. Bemmelen (*Zeitschr. anal. Chem.* 1872, 136; *Jahresb.* 1872, 881).

On the estimation of *Ammonia* in Well and River Waters, see H. Fleck (*J. pr. Chem.* [2], v. 263; *Chem. Soc. J.* [2], x. 1041).

On the detection and estimation of *Organic matter* in Water, see A. Müller (*Deut. Chem. Ges. Ber.* iii. 659; *Jahresb. f. Chem.* 1870, 875); also Wittstein (*Dingl. pol. J.* cc. 123; *Chem. Soc. J.* [2], ix. 754), also E. Schürmann (*J. pr. Chem.* [2], iv. 374; *Jahresb. f. Chem.* 1871, 876). On Frankland's method of estimation: *Chem. News*, xxv. 157.

On the determination of *Nitrogenous Organic matter*, see J. A. Wanklyn (*Chem. News*, xxiv. 10; xxv. 157); D. Campbell (*ibid.* xxiv. 19).

On the determination of the quality of *Potable Waters*, see Almén (*Deut. Chem. Ges. Ber.* iv. 750); also G. Bischof (*Zeitschr. anal. Chem.* x. 441). This paper contains descriptions and figures of the microscopic appearances presented by the evaporated residues of potable waters contaminated with various kinds of organic matter.

On the alterations of *Potable Waters*, see J. Müller (*Arch. Pharm.* [2], cxlix. 27; [3], i. 385; *Jahresb. f. Chem.* 1871, 165).

Determination of the *Hardness of Waters*: E. Reichardt (*Zeitschr. anal. Chem.* 1871, 284); A. Wagner (*Arch. Pharm.* [2], cl. 235); Gröger (*N. Jahrb. Pharm.* xxxvi. 1; *Jahresb. f. Chem.* 1872, 877); of the *Temporary Hardness*: A. Wagner (*Dingl. pol. J.* cci. 426; *Chem. Soc. J.* [2], x. 23).

For analyses of *Sea Water*, see *Jahresb. f. Chem.* 1870, 1380; 1871, 1222: of *Lake and River Water*, *ibid.* 1871, 1223; 1872, 1180: of *Spring and Mineral Waters*, *ibid.* 1870, 1382-1391; 1871, 1225-1233; 1872, 1181-1188.

On the composition of *Drainage Water*, see Voelcker (*Chem. Soc. J.* [2], ix. 276-297).

On the composition of *Water for feeding Steam-Boilers*, and the methods of *Softening* it, see J. Stingl (*Dingl. pol. J.* cvi. 304; *Jahresb. f. Chem.* 1872, 970).

WATER-GLASS. According to Flückiger (*Arch. Pharm.* [2], cxliv. 97; *Jahresb. f. Chem.* 1870, 305) the precipitate formed in solutions of water-glass by very soluble salts of potash, soda, lithia, and ammonia, consists of silica. Reintz, on the other hand (*Deut. Chem. Ges. Ber.* iv. 104) finds that soda water-glass gives with strong aqueous ammonia a precipitate containing soda and silica in the ratio $\text{Na}_2\text{O} : 4\text{SiO}_2$. The precipitate formed by a strong solution of sodium nitrate has the composition $\text{Na}_2\text{SiO}_3 + 8\text{H}_2\text{O}$. Water-glass behaves therefore with neutral salts of potassium and sodium just like soaps, excepting that the latter are precipitated by caustic potash, whereas in the water-glass solution the precipitate is produced only by ammonia. This circumstance may be made available for the preparation of perfectly pure water-glass.

On the use of *Gates* (p. 536) for the preparation of water-glass, see Scheurer-Kestner (*Compt. rend.* lxxi. 767; *Chem. Soc. J.* [2], ix. 783).

WAVELLITE. This mineral occurs as a thin coating on the cleavage-faces of amblygonite (p. 972), forming small radiate spherules, the needles of which have the form of strongly-striated prisms. An analysis by Pisani gave:

F	P ₂ O ₅	Al ₂ O ₃	H ₂ O	
2.27	84.30	38.26	26.60	= 101.42 Sp. gr. = 2.33.

(Des Cloizeaux, *Compt. rend.* lxxv. 69).

WAX. On the formation of Bees-wax, and the proportion of wax in Pollen, see *Pollen* (p. 1006).

Straw-wax.—J. König (*Deut. Chem. Ges. Ber.* iii. 566) confirms the observations of Radziejewski respecting the occurrence of wax in the straw of cereals (*1st Suppl.* 1128), and adds that it is also contained in meadow and clover hay and in pea straw. In meadow and clover hay he found 1.0 to 1.3 p.c. true fat, together with 0.4 to 0.6 p.c. wax; rye and barley-straw yielded about 0.5 p.c. fat, and the same quantity of wax. See *Fat* (pp. 506, 507).

WEBSTERITE or **ALUMINITE.** This mineral has been found in the chalk near Brighton, forming a layer about 3 feet thick, and probably filling a cleft; above

It is a ferruginous clay with nodules of limonite, flint, and isolated crystals of gypsum. The websterite is of very variable constitution, sometimes in the form of the finest white powder, appearing under the microscope as an aggregate of extremely fine crystals, sometimes in compact nodular masses resembling meerschaum (S. Percival, *Jahrbuch. f. Mineralogie*, 1871, 637).

WINE. Preservation.—To preserve wine in good condition. Pasteur (*Bull. Soc. Chim.* [2], iv. 80, 410) recommends that it be heated for some minutes in perfectly filled and tightly corked bottles, or in casks, to 60°–70° (perhaps even 45° would be high enough), in order to destroy the vitality of the cryptogamic germs, which are the cause of its deterioration. Wine thus heated is quite clear after cooling, undergoes no alteration in colour, taste, or odour, and keeps well even in half-filled bottles.

An apparatus for carrying out this process on the large scale has been constructed by Giret a. Vinas (*Dingl. pol. J.* cci. 550). It consists of two upright cylinders of tinned copper, one serving as a heating vessel, and the other as a cooler, in which the wine circulates through annular jackets of the same height as the cylinders. The wine first passes through the cooler, then passes into the heating apparatus, where it traverses the annular jacket—which is warmed externally by water to 55°–60°—thence it passes into the annular jacket of the cooler, and finally leaves the apparatus. It is essential that the wine be not heated above 60°, otherwise it acquires a boiled taste, and that the apparatus be perfectly closed to prevent the escape of any of the volatile odoriferous principles of the wine.

A table of the composition of German and other wines is given by G. Glässner (*Arch. Pharm.* [2], cxlix. 117; *Jahresb. f. Chem.* 1872, 1043).

Analysis of Wine. On the Spectroscopic examination of Wine, and its application to the detection of Adulteration, see Sorby (*Quar. Jour. of Microscopical Science*, 1869, 358; *Jahresb. f. Chem.* 931).

On methods of distinguishing between Grape and Fruit wines (made from apples, pears, gooseberries, currants, &c.), see *Zeitschr. anal. Chem.* 1871, 231; 1872, 337; *Jahresb.* 1871, 967; 1872, 936.

On the Detection of the addition of Spirit to Wine (so-called *gallisation*), see Schubert (*Zeitschr. anal. Chem.* 1870, 112; *Jahresb.* 1870, 1043).

Estimation of Free Acid.—F. Schwachhöfer (*Zeitschr. anal. Chem.* 1872, 331) estimates the quantity of free acid in red wine by mixing the wine with tincture of litmus, supersaturating with caustic baryta, and titrating back with sulphuric acid. As the point of saturation is approached, every drop of sulphuric acid added produces a red zone. For the titration 10 c.c. of wine are used; 1 c.c. baryta-solution = 0.009852 gram of tartaric acid (eq. 76), and 1 c.c. sulphuric acid = 16 c.c. of baryta-solution.

Estimation of Cream of Tartar in Wine.—P. Carles recommends for this estimation, in place of the old method of incineration, which is not exact, the process devised by Berthelot a. Fleuriou, which consists in precipitating the acid tartrate of potassium by adding to the wine an equal volume of a mixture of alcohol and ether, washing the crystalline precipitate slightly with alcohol, redissolving it in water, and estimating the tartaric acid by titration with a standard alkaline solution (*J. Pharm. Chim.* [4], xiv. 188; *Chem. Soc. J.* [2], ix. 1211).

Estimation of Sugar in Wine (Schubert, *Zeitschr. anal. Chem.* 1870, 112; *Jahresb. f. Chem.* 1870, 1037).

WINKLERITE (Breithaupt, *Jahrb. f. Mineralogie*, 1872, 816). An amorphous bluish-black to velvet-black mineral from Oria near Matril in the Sierra Almahilla, Spain, also found on the Rothenberg near Saalfeld. Hardness = 3. Sp. gr. = 3.432. An analysis by C. Winkler gave the values A, together with potash and soda, recognisable by the spectroscope. Deducting Fe_2O_3 and SiO_2 as admixtures, and reckoning the nickel with the cobalt, we obtain the values B, which Winkler represents by the formula:

Grouping these values as follows:

the whole may be regarded as an intimate mixture of malachite, pharosolite, cobaltic hydrate, and cobaltous carbonate. The mineral may have been formed by the action of calcareous water containing carbonic acid on cobalt-bloom in contact with malachite.

	CoO	NiO	CaO	FeO	Fe ² O ³	CaO	As ² O ³	CO ²	SiO ²	H ² O
A.	22.91	2.38	12.31	10.24	8.05	6.85	10.22	10.87	2.64	14.06 = 100.63
B.	33.10	—	13.89	10.88	—	5.92	10.55	10.29	—	14.80 = 100
C.	33.17	—	14.11	11.20	—	4.97	10.23	11.73	—	14.06 = 100

WINKWORTHITE (H. How, *Phil. Mag.* [4], xli. 270). A mineral occurring in colourless transparent nodules, some as big as a nut, in the gypsum of Winkworth, Hants County, Nova Scotia. The numbers in the two following analyses are intermediate between those required by the formulæ:

$11\text{CaO}, \text{SiO}_2, 9\text{SO}_3, 3\text{B}_2\text{O}_3, 20\text{H}_2\text{O}$, and $11\text{CaO}, \text{SiO}_2, 8\text{SO}_3, 4\text{B}_2\text{O}_3, 20\text{H}_2\text{O}$:

CaO	SO ₃	SiO ₂	B ₂ O ₃ *	H ₂ O
31.66	36.10	3.31	10.13	18.80 = 100
31.14	31.51	4.08	14.37	18.00 = 100

* Determined by loss.

Kenngott (*Jahrb. f. Mineralogie*, 1872, 300) shows by calculation that these formations are mixtures of silico-boracalcite, 77.87 p.c., and gypsum, 67.75 p.c.

WINTERGREEN OIL. According to J. Broughton (*Pharm. J. Trans.* [3], ii. 281) the oil of *Andromeda Leschenaultii* consists of methyl-salicylic acid, and is nearly identical with Canadian wintergreen oil.

WOOLMINITE. See BAUXITE (p. 126).

WOHLERITE. See TANTALATES (p. 1146).

WOLLASTONITE. G. vom Rath (*Jahresb. f. Mineralogie*, 1872, 217) describes an outcast from Monte Somma, consisting of a nucleus of compact limestone surrounded by a shell of wollastonite arranged in layers perpendicular to the circumference. Between the shell and the nucleus there is a zone of limestone not sharply defined on its inner surface, rich in wollastonite fibres (58.49 p.c. wollastonite) whilst the central mass contains only 25.33 p.c. of silicate. There is here abundant evidence of a metamorphism, proceeding from without inwards, of carbonate into silicate. An analysis of the wollastonite (sp. gr. = 2.853) gave:

SiO ₂	Al ₂ O ₃	CaO	MgO	Loss by ignition
51.31	1.37	45.66	0.73	0.75 = 90.82.

WOOD. On the Distillation of Wood, see Watson Smith (*Chem. Soc. J.* [2], ix. 1101).

WOOL. On the Action of Alkalis upon Wool, see LANUGINIC ACID (p. 723), and SERICIC ACID (p. 1080).

A method of distinguishing between wool and silk, founded on the presence of sulphur in wool, is given by E. Kopp (*Moniteur Scientifique*, [3], i. 683). The (white) sample to be tested for wool is immersed in a solution of lead oxide in potash-ley, whereupon, if wool is present, black lead sulphide will be produced. See further, *Dingl. pol. J.* cxcv. 563; *Chem. News*, xxvi. 100.

On the Composition of Sheep's Wool, and on the Extraction of Fat-acids together with Wool-grease from the Soap-waters of Wool-washing, see Märker a. Schulze (*J. pr. Chem.*, cviii. 193; *Jahresb. f. Chem.* 1870, 811; *Dingl. pol. J.* cxcv. 173; cxcvi. 571; *Jahresb. f. Chem.* 1869, 811; 1870, 1232).

The process of washing and dyeing wool, devised by Ensom a. Spence, is described by C. Bollé (*Dingl. pol. J.* cci. 435; *Jahresb.* 1871, 1104).

On Dyeing Woollen Cloth with Amaranth-colour, see Pfundheller (*Dingl.* cci. 179; *Jahresb.* 1871, 1100); with Scarlet, B. Jegel (*Dingl.* cciii. 422; *Jahresb.* 1872, 1072).

Wool-grease.—On the Composition of the Grease (*suint*) from Sheep's Wool, see CHOLESTERIN (p. 330).

The substance there mentioned as separating in white-flocks from solution in alcohol has since been shown by Schulze to be an isomeride of cholesterol (*J. pr. Chem.* [2], vii. 163; *Chem. Soc. J.* [2], xi. 1219).

WORMWOOD OIL. On the Index of Refraction of this oil, see LIGHT (p. 740).

WULFENITE. On Chromo-wulfenites, see Schauf (*Proc. Roy. Soc.* 1871, 461; *Chem. Soc. J.* [2], ix. 601).

X

XANTHAMIDE. Phenyl-xanthamide, $\text{CS}(\text{C}^6\text{H}_5)\text{HN}(\text{C}^6\text{H}_5)$ O, is formed, together with xanthic acid and free sulphur, by the action of aniline on ethyldisulphocarbonic sulphide (v. 499):

A portion of the xanthic acid is further acted upon by the excess of aniline present, forming diphenylsulphocarbamide:

Phenyl-xanthamide forms triclinic crystals, more soluble in alcohol than sulphocarbamide (A. W. Hofmann, *Deut. Chem. Ges. Ber.* iii. 172).

XANTHINE. This substance has been found by G. Lebon (*Compt. rend.* lxxiii. 47) in a urinary calculus consisting of a superficial layer 1 mm. thick of calcium phosphate mixed with ammonium-magnesium phosphate, an equally thin layer of calcium oxalate, and a nucleus, forming the greater part of the stone, consisting of xanthine with a small quantity of calcium urate.

XANTHOCOBALE COMPOUNDS. See COBALT (p. 364).

XANTHOPHYLLITE. In the xanthophyllite of the Schischimskian mountains near Slatoust, Jeremejew has observed microscopic diamonds of varying size irregularly distributed through the plates of the mineral (*Jahresh. f. Mineralogie*, 1871, 276; *Chem. Soc. J.* [2], ix. 667). In connection with these observations Jeremejew has collated some of the older statements regarding xanthophyllite, from which it appears that this mineral occurs not only of yellow shades, but also colourless, brownish, light gray and yellowish green. Hardness = 5. Sp. gr. = 3.035 – 3.062. Optically uniaxial.

A. Knop (*Jahresh. f. Mineralogie*, 1872, 785) has published several analyses of xanthophyllite by G. Wagner (a), O. Schifferdecker (b), and himself (c. and d). On account of the great variations in the amount of water (two other specimens gave 2.33 and 3.83 p.c.), Knop regards it as unessential, and assigns to xanthophyllite the formula $2(\text{RO}.\text{SiO}_2) + 3(\text{RO}.\text{R}'\text{O})$.

SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	H_2O
17.42	44.18	3.53	11.95	20.61	2.61 = 100.80
17.7	43.6	2.9	11.5	20.9	2.5 = 99.1

XYLENE. $\text{C}^6\text{H}_{10} = \text{C}^6\text{H}(\text{CH}_3)_2$. On the Xylenes and Cumenes of Coal-tar, see CUMENE (p. 402).

Orthoxylene is produced by heating liquid bromotoluene, dissolved in pure benzene, with methyl iodide and sodium. The product, purified by fractional distillation, boils at 141° – 143° (the column of mercury being wholly in the vapour), has a faint and agreeable aromatic odour, and does not solidify at -22° . By oxidation with dilute nitric acid, it yields paratoluic acid (m. p. 178°) and orthotoluic acid (m. p. 104° – 106°), in the proportion of about 1 to 3. With fuming nitric acid either in the cold or at boiling heat, it yields only liquid compounds, from which after some weeks a few crystals separate (Jannasch & Häbner, *Zeitschr. f. Chem* [2], vii. 706).

Isoxylene or *Metaxylene*.—This modification may be obtained nearly pure by heating commercial xylene (which is a mixture of isoxylene and methyl-toluene or paraxylene) with dilute nitric acid, the methyl-toluene being thereby oxidised, while the isoxylene remains unattacked. From this isoxylene, *dinitro-isoxylene*, and *ammonio-dinitroisoxylene* or *nitroxylidine* (1st Suppl. 294, 1181) were prepared. The latter yields, through the medium of the diazo-compound, a β -nitroxylene $\text{C}_8\text{H}_7\text{NO}$, which solidifies at low temperatures, melts at $+2^\circ$, boils at 237° – 238° , and has a sp. gr. of 1.126 at 17.6° . By oxidation with chromic acid it is converted into nitro-toluic acid (1st Suppl. 1195). By reduction it yields *p*-xylylidine (p. 1205).

Chloroxylenes. *Monochloroxylene*, or *Xylol Chloride*, $C^6H^4 \begin{Bmatrix} OH \\ CH^2Cl \end{Bmatrix}$, is produced by the action of chlorine on coal-tar xylene. When heated with water to 200° in sealed tubes, it splits up into dimethyl-anthracene, $C^{10}H^{14} = C^4H^4(C^2H^5)_2$, xylol-xylene, $C^8H^{10} = C^6H^4(C^2H^5)_2$, and hydrochloric acid:

See ANTHRACENE (p. 84).

Dichloroxylene, or *Xylylene Chloride*, $C^6H^4Cl_2 = C^6H^4 \begin{Bmatrix} CH^2Cl \\ CH^2Cl \end{Bmatrix}$ (called *tollylene chloride* by Grimaux), is produced by the action of chlorine at 140° on methyl-toluene (paraxylene), (Grimaux, *Compt. rend.* lxx. 1363). It may also be obtained by the action of chlorine on commercial xylene at the boiling heat, though less advantageously, as commercial xylene contains but a small proportion of methyl-toluene (v. 1057).

Dichloroxylene oxidised by chromic acid mixture is converted into terephthalic acid. Heated with water to 170° – 180° it is resolved into hydrochloric acid and dihydroxyl-xylene or xylylene glycol, $C^6H^4(OH)_2$. Heated with sodium acetate, it yields the monoacetate and diacetate of xylylene, and with sodium benzoate, the monobenzoate of xylylene.

Dibromoxylene or *Xylylene Bromide*, $C^6H^4Br_2 = C^6H^4(CH^2Br)_2$, is prepared by dropping into boiling methyl-toluene $2\frac{1}{2}$ times its volume of bromine, washing the cooled mass with ether, and recrystallising from alcohol. It is also formed by distilling xylylene glycol with hydrobromic acid. It dissolves sparingly in ether, easily in chloroform, and crystallises therefrom in rhombic laminae which melt at 145° – 147° .

Di-iodoxylene, or *Xylylene Iodide*, $C^6H^4(CH^2I)_2$, is obtained by boiling xylylene glycol for a few minutes with strong hydriodic acid (b. p. 127°). It forms slender needles, slightly soluble in ether, easily soluble in boiling alcohol and in chloroform. It quickly turns yellow when exposed to the air, melts and becomes coloured at about 170° , and decomposes at a higher temperature.

Dihydroxyl-xylene, or *Xylylene-glycol*, $C^6H^4 \begin{Bmatrix} CH^2OH \\ CH^2OH \end{Bmatrix}$, is prepared by heating the chlorine or bromine compound with 30 times its weight of water to 170° – 180° , concentrating the aqueous solution, neutralising with alkaline carbonate, and extracting the glycol with ether. It crystallises from ether in shining needles, dissolves easily in water, alcohol and ether; melts at 112° – 113° . With chlorine, bromine, or iodine, it yields the chloride, bromide, or iodide of xylylene. By sulphuric acid and potassium dichromate it is oxidised to terephthalic acid.

Condensed Glycols appear to be formed by heating xylylene chloride or bromide with water to 200° . They are yellow masses insoluble in all menstrua.

Monobenzoxy-xylene, or *Xylylenemonobenzoate*, $C^6H^4 \begin{Bmatrix} OH \\ OC^2H^5O \end{Bmatrix}$, obtained by heating the dichloride with an alcoholic solution of sodium benzoate, forms long thin needles which melt at 73° – 74° , and dissolve readily in alcohol and in ether.

Diacetoxy-xylene, or *Xylylene diacetate*, $C^6H^4(OC^2H^5O)_2$, obtained by heating the dichloride with alcoholic sodium acetate to 150° , crystallises in hard shining laminae, having a hot camphorous taste, easily soluble in alcohol and ether. By distillation it appears to yield the monoacetate (Grimaux).

XYLIDINE, $C^6H^4N = C^6H^4NH^2 = C^6H^4(NH^2) \begin{Bmatrix} CH^2 \\ CH^2 \end{Bmatrix}$. Hofmann & Martius (*Deut. Chem. Ges. Ber.* ii. 411) have obtained from commercial aniline oil, by fractional distillation, a xylidine boiling constantly at 212° . This xylidine does not yield colouring matters by oxidation, either alone or when mixed with toluidine, but when mixed with pure aniline it yields by the ordinary treatment a colouring matter resembling rosaniline (Hofmann, *ibid.* 378).

By nitrating synthetically prepared ethylbenzene, and reducing the nitro-compound with tin and hydrochloric acid, a xylidine was obtained, likewise boiling at 212° but nevertheless not identical with the xylidine above mentioned; it smells like aniline prepared from indigo, its salts are more soluble, and it does not yield colouring matters by oxidation either alone or with toluidine or aniline (Hofmann).

Tavildarow (*Deut. Chem. Ges. Ber.* ii. 558; *Zeitschr. f. Chem.* vi. 418) has prepared xylidine (distinguished as β) from coal-tar xylene (purified by prolonged boiling with dilute nitric acid), by nitration and reduction with tin and hydrochloric acid. The xylidine, separated by potash, was obtained as a colourless liquid, having a sp. gr. of

0.985 at 18.5°, and boiling at 216°; 100 pts. water at 18° dissolve 3.319 pts. of it. The *oxalate* crystallises well and dissolves to the amount of 3.846 pts. in 100 pts. water at 21.5°. The *acetyl-derivative* crystallises in needles and melts at 128°.

The crude xylidine, when distilled, yielded between 235° and 246°, a solid body melting at 89°, which gave with hydrochloric acid a compound having the composition $(C^8H^7Cl)^2N.HCl$ (Tawildarow).

Bromoxylidine, $C^8H^7Br.NH^2$, is formed from acetobromoxylide, $C^8H^7Br.NH(C^2H^3O)$ (1st Suppl. 1131), by distillation with soda-ley. Should it be contaminated with dibromoxylidine, it must be dissolved in hydrochloric acid, the solution evaporated to dryness, the monobromoxylidine hydrochloride dissolved out by hot water, and the free base precipitated by ammonia. Bromoxylidine is insoluble in cold, and but slightly soluble in hot water. It dissolves easily in alcohol and ether, and crystallises from dilute alcohol in white microscopic needles melting at 96°-97°. The *hydrochloride* forms white needles; its aqueous solution forms with platinic chloride a light yellow crystalline precipitate (Genz, *Deut. Chem. Ges. Ber.* iii. 226).

Acetodibromoxylide is formed by agitating acetoxylide with the calculated quantity of bromine-water. It is insoluble in water, and crystallises from alcohol in white shining crystals (Genz).

Dibromoxylidine, $C^8H^7Br^2.NH^2$, produced by distilling aceto-dibromoxylide with potash-ley, crystallises from alcohol in needles. Its hydrochloride gives off hydrochloric acid when boiled with water (Genz).

Phenylxylidine, $C^8H^7.NH(C^6H^5)$, is produced by heating xylidine with aniline hydrochloride. It melts at 52°, boils at 278°-282° under a pressure of 485 mm. and at 173° under 15 mm. Soluble in alcohol, ether, benzene, and light petroleum oil. The *hydrochloride* is best obtained by passing hydrochloric acid gas into a solution of the base in benzene (Girard a. Vogt, *Bull. Soc. Chim.* [2] xviii. 67).

Tolylxylidine, $C^8H^7.NH(C^7H^7)$, crystallises from alcoholic solution in long, white, silky, light needles melting at 70°. It boils at 194° in a vacuum, and at 298°-300° under a pressure of 487 mm. (Girard a. Vogt).

Di-xylidine, $(C^8H^7)^2HN$, obtained by heating xylidine with its hydrochloride, is a mixture of isomeric bodies, one of which is liquid, while the other is crystalline and melts at 162° (Girard a. Vogt).

Naphthylxylidine, $C^8H^7.NH(C^{10}H^7)$, obtained by heating xylidine hydrochloride with naphthylamine, is a thick liquid quickly turning brown and boiling at 243°-246° under a pressure of 15 mm. (Girard a. Vogt).

XYLYL-CARBAMIDE, or **XYLYL-UREA**, $N^2H^4(CO)C^8H^7$, is produced on mixing a solution of xylidine sulphate with potassium cyanate. After washing with warm water and recrystallisation from alcohol, it forms white needles melting at 186° (Genz).

Di-xylidylcarbamide, $N^2H^4(CO)(C^8H^7)^2$, formed by heating urea with three times its weight of xylidine, is insoluble in water, slightly soluble in boiling alcohol, ether, benzene, chloroform, and acetic acid, and crystallises from hot alcohol in snow-white felted needles, which do not melt at 250° (Genz).

XYLYL-CARBIMIDE, or **XYLYL ISOCYANATE**, $N(CO)^2(C^8H^7)$. See CYANIC ETHERS (p. 407).

XYLYL-GUANIDINE (DI-), $C(C^8H^7)^2H^3N^2$, formed by the action of dry cyanogen chloride on xylidine, forms large white plates sparingly soluble in cold, more easily in hot water, very soluble in alcohol and ether. Its *platinichloride* has the composition $2[C(C^8H^7)^2H^3N^2.HCl].PtCl^4$. A base having the same composition is formed by the mutual action of sulphocarbonyl, alcoholic ammonia, and lead oxide (Genz).

XYLYLENE ALCOHOL and ETHERS. See XYLENE (p. 1209).

XYLYL-NAPHTHYLAMINE. See NAPHTHYL-XYLIDINE, &c. (*supra*).

XYLYL-URETHANE, $CO \begin{Bmatrix} NH.C^8H^7 \\ OC^8H^7 \end{Bmatrix}$. See CARBAMATES (p. 263).

XYLYL-XYLENE, $C^8H^7(C^8H^7)$, is formed, together with dimethylxylidine, by heating xylidyl chloride with water in a sealed tube. See ANTHRACENE (p. 1208).

Y

YEAST. See FERMENTATION (p. 516).

YTTRIUM and **ERBIUM** (Cleve & Hoeglund, *Bull. Soc. Chim.* [2], xviii. 193, 289). The oxides of these metals were prepared from gadolinite and separated from one another by the method of Bahr & Bunsen (v. 721).

The atomic weights of the metals, determined by the analysis of the sulphates, are $Y = 50.7$; $Er = 113.7$. Bahr & Bunsen found $Y = 61.7$; $Er = 112.6$.

An attempt to prepare the metals by electrolyzing the fused chlorides, or by reducing the chlorides by sodium, was only partially successful.

Yttrium Salts. These salts are colourless; their solutions do not give an absorption-spectrum, and they are, as a rule, less soluble than the corresponding salts of erbium. Both yttrium and erbium salts are precipitated by barium carbonate. The hydrate of yttrium is a white, gelatinous precipitate, obtained by the addition of a fixed alkali to a salt of yttrium. When calcined at a white heat, it is converted into yttrium oxide, a yellowish-white powder, very readily soluble in acids, even after ignition.

Yttrium Chloride, $YCl_3 + 4H_2O$, forms deliquescent prisms soluble in alcohol, insoluble in ether. When heated it loses hydrochloric acid, but the anhydrous chloride can be prepared by fusing together a mixture of hydrated chloride and sal-ammoniac.

The bromide, $YBr_3 + 6H_2O$, and the iodide closely resemble the chloride in appearance and solubility. The iodide is unstable, and rapidly becomes brown when exposed to the air.

Fluoride, YF_3 .—Heavy, white, hygroscopic powder, but slightly soluble in dilute acids.

Nitrate, $Y(NO_3)_3 + 4H_2O$.—Occurs in large colourless crystals, easily soluble in water, alcohol, and ether. It is unalterable in the air, but loses 2 mols. of water when dried at 100° .

Chlorate, $Y(ClO_3)_3 + 6H_2O$.—The crystals of this salt are small colourless prisms, exceedingly deliquescent, soluble in alcohol, but very slightly so in ether.

Perchlorate, $Y(ClO_4)_3 + 6H_2O$ (?).—Transparent crystals, very deliquescent, slightly soluble in alcohol.

Bromate, $Y(BrO_3)_3 + 6H_2O$.—Colourless needles, very soluble in water, slightly soluble in alcohol, almost insoluble in ether. It decomposes at 100° – 110° . The iodate is a very definite salt, but not crystalline.

Periodate.—Two periodates are formed, according as the periodic acid employed in their preparation is in excess or not. The salt marked (a) is the most definite:

Sulphate, $3Y_2SO_4 + 8H_2O$.—Small transparent crystals, which lose their water of crystallisation at 115° . 100 pts. of water at 15.5° dissolve 9.3 pts. of crystallised, and 15.2 pts. of anhydrous sulphate; but on raising the temperature of the latter solution, a portion of the crystallised salt is deposited.

Sulphocyanate, $Y(CNS)_3 + 4H_2O$.—Well-defined prisms, soluble in water, alcohol, and ether, and permanent in the air.

Platinosocyanide, $Y(CN)_3Pt + 7H_2O$.—Like many platinosocyanides this salt crystallises in large, well-defined, dichroic crystals, red by transmitted light, and green or violet-blue by reflected light. It is easily soluble in water, but alcohol deprives it of a portion of its water of crystallisation, and changes its colour to a lemon-yellow.

Double Sulphates.—Two potassium salts were obtained, to which the formulae $YK^+3SO_4^+$ and $Y^+K^+3SO_4^+$ were assigned, but the analytical results did not agree very accurately with the calculated percentages. The sodium and ammonium salts were much more definite, and the formulae $Y^+Na^+(SO_4^+)_2 + 2H^+O$ and $Y^+(NH_4^+)(SO_4^+)_2 + 6H^+O$ may be regarded as correctly representing their composition.

The *sulphite*, $\text{YSO}^3 + \text{H}^2\text{O}$, is also a definite salt, crystallising in microscopic needles. It absorbs oxygen rapidly from the air.

Selenate, $\text{YSeO}^4 + 3\text{H}^2\text{O}$ (?)—Large well-developed crystals, very soluble, and losing a portion of water of crystallisation in dry air.

Selenite, $\text{Y}^2\text{H}^4(\text{SeO}^3)^4$.—This salt occurs either as a white crystalline powder, or in the form of flattened microscopic prisms, according to the manner in which it has been prepared. It is soluble in mineral acids.

Phosphates.—The *metaphosphate*, $\text{Y}(\text{PO}^3)^2$, is a heavy crystalline powder insoluble in water and acids. The *pyrophosphate*, $\text{Y}^2\text{H}^2.2\text{P}^2\text{O}^7 + 7\text{H}^2\text{O}$, is a soluble salt; the *orthophosphate*, $\text{Y}^2(\text{PO}^4)^3 + 4\text{H}^2\text{O}$, is very sparingly soluble.

Carbonate, $\text{YCO}^3 + \text{H}^2\text{O}$.—Heavy white powder, indistinctly crystalline, and perfectly insoluble in water.

Acetate, $2\text{Y}(\text{C}^2\text{H}^3\text{O}^2)^2 + 5\text{H}^2\text{O}$.—Crystallises from its solution in colourless rhombohedrons, very soluble in warm water, but very sparingly in cold. It is permanent in the air.

Oxalate, $\text{YC}^2\text{O}^4 + \text{H}^2\text{O}$.—White crystalline powder, readily soluble in water acidulated with hydrochloric acid. It dissolves easily in concentrated solutions of potassium oxalate, forming the double salts, $\text{Y}^2\text{K}^2(\text{C}^2\text{O}^4)^7 + 12\text{H}^2\text{O}$ and $\text{Y}^2\text{K}^2(\text{C}^2\text{O}^4)^4 + \text{H}^2\text{O}$.

Double Carbonates, $\text{Y}^2\text{Na}^2(\text{CO}^3)^4 + 4\text{H}^2\text{O}$ and $\text{Y}^2(\text{NH}^4)^2(\text{CO}^3)^4 + 3\text{H}^2\text{O}$.

Succinate, $\text{YC}^2\text{H}^3\text{O}^4 + x\text{H}^2\text{O}$ (?).

Tartrate, $\text{Y}^2\text{H}^2(\text{C}^4\text{H}^3\text{O}^6)^4 + 6\text{H}^2\text{O}$.—White crystalline precipitate, very slightly soluble in water.

Erbium Salts. These salts resemble those of yttrium in most of their properties. The only well-marked distinctive characteristics are the following.

The salts of erbium have a beautiful rose colour, and their solutions give absorption-bands. The appearance of their spectrum is quite different from that of didymium-salts. Erbium oxide dissolves with great difficulty, even in concentrated acids. A solution of ammonium oxalate dissolves only traces of yttrium oxalate, but erbium oxalate dissolves in it with great readiness, forming a well-defined crystallisable double salt.

Erbium Salts.

Chloride	$\text{ErCl}^2 + 4\text{H}^2\text{O}$
Bromide	$\text{ErBr}^2 + \text{H}^2\text{O}$
Sulphocyanate	$\text{Er}(\text{CNS})^2 + 4\text{H}^2\text{O}$
Chlorate	$\text{Er}(\text{ClO}^3)^2 + 6\text{H}^2\text{O}$ (?)
Iodate	$\text{Er}(\text{IO}^3)^2 + 2\text{H}^2\text{O}$
Sulphate	$(\text{ErSO}^4)^2 + 8\text{H}^2\text{O}$
Selenite	$\text{Er}^2\text{H}^4(\text{SeO}^3)^4 + 3\text{H}^2\text{O}$
Pyrophosphate	$\text{Er}^2\text{H}^2(\text{P}^2\text{O}^7)^2 + 7\text{H}^2\text{O}$
Acetate	$\text{Er}(\text{C}^2\text{H}^3\text{O}^2)^2 + 3\text{H}^2\text{O}$
Succinate	$(\text{ErC}^2\text{H}^3\text{O}^4)^2 + 3\text{H}^2\text{O}$
Double potassium sulphate	$\text{ErK}^2(\text{SO}^4)^2$
" potassium oxalate	$\text{Er}^2\text{K}^2(\text{C}^2\text{O}^4)^7 + 12\text{H}^2\text{O}$
" ammonium oxalate	$\text{Er}(\text{NH}^4)^2(\text{C}^2\text{O}^4)^4 + 5\text{H}^2\text{O}$
Fluoride	ErF^3
Ferrocyanide	$\text{K}^2\text{Er}^2\text{C}_6\text{Fe}^2 + x\text{H}^2\text{O}$
Nitrate	$\text{Er}(\text{NO}^3)^3 + 4\text{H}^2\text{O}$
Bromate	$\text{Er}(\text{BrO}^3)^3 + 6\text{H}^2\text{O}$
Periodate	$\text{Er}^2\text{I}^2\text{O}^8 + 2\text{H}^2\text{O}$
Sulphite	$\text{ErSO}^3 + \text{H}^2\text{O}$
Orthophosphate	$\text{Er}^2(\text{PO}^4)^3 + 2\text{H}^2\text{O}$
Carbonate	$\text{Er}^2 \begin{pmatrix} \text{OH} \\ (\text{CO}^3)^2 + \text{H}^2\text{O} \\ \text{OH} \end{pmatrix}$
Oxalate	$\text{ErC}^2\text{O}^4 + 2\text{H}^2\text{O}$
Platinocyanide	$\text{Er}(\text{CN})^4\text{Pt} + 7\text{H}^2\text{O}$

Since most of the salts of yttrium and erbium contain the same quantity of water of crystallisation as the corresponding salts of magnesium and zinc, and since the sulphates are isomorphous with cadmium sulphate, it is probable that these elements might be arranged in the same series as magnesium and its congeners; but it will be noticed that they do not give the double sulphates so characteristic of the magnesium

series, $R'R''(SO_4)_2 + 6H_2O$. In addition to this, yttrium and cerium enter into numerous combinations with a triple atomic weight, which would seem to imply that they are trivalent elements. The question cannot as yet be settled by the specific heat of the metals, as they have not been obtained in the pure state.

YTTROCERITE. The composition of this mineral, according to two analyses by Rammelsberg (*Deut. Chem. Ges. Ber.* iii. 657), is:

CaO	CeO ^o	YO	Loss by ignition	Sp. gr.
47.27	9.35	14.87	2.52	3.863
49.32	16.14		undetermined	undetermined

From these numbers (with the atomic weights Ce = 92; Y = 64) Rammelsberg deduces the formula $2(CaF_2.2YF_2.9CaF_2) + 3H_2O$.

The cerose-ceric oxide contained nearly half its weight of lanthanum and didymium oxides, and the substance designated by YO contained 30 p.c. of a base precipitable by barium carbonate and 70 p.c. of a base not thus precipitable.

YTTROTANTALITE. See TANTALATES (p. 1146).

Z

ZEONERITE. See URANIC ARSENATES (p. 1190).

ZINC. *Atomic Weight, 65.*—*Preparation.*—Pure zinc may be prepared by the electrolysis of an ammoniacal solution of zinc sulphate, a zinc plate being used as the positive, and a T-shaped copper wire as the negative electrode. On passing the current of two Bunsen's elements through the liquid, crystals of zinc form at the ends of the T; they may be removed with a pair of forceps, and washed with dilute ammonia (J. Myers, *Compt. rend.* lxxiv. 196).

On the *Heat of Oxidation of Zinc*, see HEAT (p. 617).

On the action of Zinc on *Nitric acid* and on mixtures of this acid with *Hydrochloric and Sulphuric acids*, the ultimate products of which are Ammonia and Sulphate, Nitrate or Chloride of Zinc, see H. Sainte-Claire Deville (*Compt. rend.* lxx. 20, 580; *Jahresb. f. Chem.* 1870, 20).

On the action of Zinc on *Sulphurous acid*, see SULPHUR-ACIDS (p. 1134).

Estimation of Zinc.—J. H. Talbott (*Chem. News*, xxii. 229) precipitates the zinc from a hot neutral or nearly neutral solution with *sulphide of sodium* or *ammonium*, avoiding the use of a great excess. The precipitate then becomes very dense, especially after further boiling, and settles down quickly. After washing and drying it is ignited with free access of air, in a porcelain crucible, first gently, and afterwards very strongly, whereby, especially on addition of a few lumps of ammonium carbonate, pure zinc oxide is obtained.

In the *volumetric estimation* of zinc by solution of sodium sulphide, A. Deuss (*Zeitschr. anal. Chem.* ix. 367; *Jahresb. f. Chem.* 1870, 1002) recommends, as a delicate indicator of the termination of the reaction, paper saturated with *cobalt chloride*. On moistening this paper with the zinc solution, before the titration is complete, a white circle is formed, pale blue on the circumference; but if the slightest excess of sodium sulphide is present, a dark sharply defined colour is produced in the middle of the ring, as soon as the paper has absorbed the drop. The test-papers are prepared by saturating strips of filter-paper $2\frac{1}{4}$ inches broad, and 10 to 12 inches long, with a solution of cobalt chloride containing 0.35 gm. CoO in 100 c.c.

Hugo Tamm (*Chem. News*, xxiv. 148) estimates zinc by treating the solution with *ammonia* till the precipitate first formed is redissolved, then adding hydrochloric acid to acid reaction, and precipitating with ordinary *sodium phosphate*. A bulky precipitate of zinc phosphate is thereby produced, which quickly settles down after boiling for a short time, and may be easily filtered and washed. After drying at 100° it has the formula $Zn(NH_4)PO_4$. At a red heat it is converted into pyrophosphate, $Zn_2P_2O_7$, but as the ignition is attended with some loss of zinc, it is better to calculate the zinc from the weight of the precipitate dried at 100° . The precipitation of the zinc is complete when the supernatant liquid is no longer clouded on addition of

sodium phosphate, but it is best to add at once a quantity of the reagent sufficient to produce a slight alkaline reaction, and then to leave the liquid in a warm place for 10-12 hours. It must also be observed that the precipitated zinc phosphide is not quite insoluble in water, and is apt to stick to the sides of the vessel. In estimating zinc by this method, it is necessary to ensure the absence of cobalt, nickel, manganese, calcium, and magnesium, and it is advisable to test the purity of the precipitate by a qualitative examination.

On the Estimation of Zinc in Blends, see A. Julien (*Chem. News*, xxv. 16; *Jahresb. f. Chem.* 1872, 911).

On the Separation of Zinc from Lead, see p. 726 of this volume; from Nickel, p. 849.

Zinc Iodide, ZnI_2 . Compounds of this iodide with aniline and toluidine are obtained by mixing the two bodies in alcoholic solution. The compounds, $2C_6H_5N.ZnI_2$ and $2C_6H_4N.ZnI_2$, are both soluble in alcohol and crystallise in needles (H. Vohl, *Arch. Pharm.* [2], cxlviii. 201).

Oxide, ZnO . On the effect of Calcination on the Heat evolved in the solution of this oxide in acids, see HEAT (p. 617).

On the Change of Colour produced in Zinc Oxide by Heat, see LIGHT (p. 747).

Phosphide. A zinc phosphide, probably having the composition $ZnHP$, is formed by passing phosphine gas into a well-cooled ethereal solution of zinc-ethyl (Drechsel a. Finkelstein, *Zeitschr. f. Chem.* [2], vii. 375). On the Formation of Organic Phosphines by the action of this compound on Iodide of Ethyl, &c., see PHOSPHINES (p. 951).

Sulphide, ZnS . According to A. Wagner (*Dingl. pol. J.* cxvii. 334) the formation of this compound by passing hydrogen sulphide over air-dried zinc hydrate takes place very slowly. When the sulphide thus formed is exposed to the air, it continues to give off hydrogen sulphide, and reproduces zinc oxide even after three months, this result being due, not to the action of carbonic oxide, which, according to Wagner, does not decompose sulphide of zinc, but to a reaction of the zinc sulphide with water.

On the crystalline form of native Zinc Sulphide (blende), see Sadebeck (*Jahrb. f. Mineralogie*, 1870, 224; 1872, 644; *Jahresb. f. Chem.* 1869, 1194; 1872, 1093); and Klein (*Jahresb.* 1871, 1126; 1872, 1093).

Zinc blende is decomposed by iodine only at high temperatures, best at 200° ; in presence of water a small quantity of sulphate is formed (Fihol a. Molhies, *Ann. Chim. Phys.* [4], xxii. 58); also v. Lasaulx (*Jahresb. f. Chem.* 1870, 1272).

On the Roasting of Argentiferous Blendes, see Simonet (*Ann. Min.* [6], xvii. 27; *Jahresb.* 1870, 1085).

ZINC-GREEN. Green pigments are obtained by mixing zinc oxide with cobalt sulphate, boiling with water, drying, and heating the residue to redness. 5 pts. zinc oxide and 1 pt. cobalt sulphate yield a dark green; 10 pts. zinc oxide and 1 pt. cobalt sulphate a grass-green, the colour becoming still lighter when the quantity of zinc oxide is again doubled. The latter colour may be used as a substitute for Schweinfurt green, and as a coating for plaster.

ZINC-SPAR. A massive zinc-spar from Raibl in Carinthia was found by E. Ludwig (*Min. Mittl.* 1871, 55) to contain:

CO_2	SiO_2	ZnO	FeO	H_2O	
31.32	0.27	59.59	7.42	1.44	= 1000.04

Iron-Zinc-spar.—A greyish indistinctly schistose mass from Ain Saffre, province of Constantine, Algeria, is regarded by Flajolot (*Ann. Min.* [6], xx. 30) as an argillaceous variety of iron-zinc-spar. Analysis gave:

$ZnCO_3$	$FeCO_3$	$MnCO_3$	$CaCO_3$	$MgCO_3$	Clay
43.05	28.60	5.10	2.05	2.10	19.20 = 100.

ZIRCON. This mineral is found in the hyperstheneite of the Radev valley near Hamburg, in very small crystals of the combination $\infty P.P.3P3$, of a white to reddish-white colour, and strong adamantine lustre. The zircon, which is imbedded for the most part in labradorite, resembles in every respect that which is found in such abundance in the gold sand of Columbia, and sparsely in the gold sand of the Grails, and renders it highly probable that both these zircons are from a matrix similar to the Harts rock (Gustav Rose, *Jahrb. f. Min.* 1871, 77).

The following analyses of zircons are by H. Cochrane (*Chem. News*, xxy. 408).

1. Ceylon, colourless; 2. Ceylon, yellowish; 3. Norway, dark yellowish; 4 and 5. Ceylon, colourless; 6. Norway, dark yellow-brown; 7. Ceylon, reddish-brown.

SiO ²	33.90	32.87	32.53	33.05	33.86	33.61	33.81
ZrO ²	64.80	64.25	64.05	66.71	64.25	64.40	66.32
Fe ² O ³	—	2.04	2.85	trace	1.08	0.90	trace
	98.70	99.16	99.43	99.76	99.19	98.91	100.13

A. H. Church (*Chem. News*, xxiii. 78) describes zircons (hyacinths) from Mudjee in New South Wales. Sp. gr. = 4.704; after ignition, attended with decoloration, 4.699.

The remarkable black bands in the spectra of certain zircons, now known to be due to the presence of certain compounds of zirconia with uranic oxide (1st Suppl. 1135), were first observed by Church in 1866 (*Chem. News*, xix. 121).

ZIRCONIA, ZrO². B. Franz (*Deut. Chem. Ges. Ber.* iii. 58) prepares this earth by fusing zircon with acid potassium sulphate, and lixiviating the pulverised melt with boiling water acidulated with sulphuric acid, whereby the basic sulphate, 3ZrO².SO³, is obtained as insoluble residuum. This salt is added by small portions to melting sodium hydrate; the melt is lixiviated with cold water; and the undissolved zirconia, still contaminated with soda, is dissolved in hot strong sulphuric acid, filtered and precipitated by ammonia.

Zirconia crystallises from fused phosphorus salt in combinations of the quadratio system, ∞ P.O.P, very much like cubes. From fused borax, zirconia crystallises in rather large well-defined, transparent, colourless, many-faced crystals, formed of a primary prism, a pinacoid parallel to the principal axis, and two domes. The dome normal to the vertical pinacoid forms an angle of 90°. A brilliant coloured polarisation is seen in the direction normal to the pinacoid. Sp. gr. = 5.42 (Knop, *Ann. Ch. Pharm.* clvii. 363; *Jahresb.* 1871, 322; *Chem. Soc. J.* [2], ix. 804).

ZIRCONIUM. Metallic zirconium prepared by Troost's process from the pure zirconia above described, exhibited the properties mentioned in vol. v. p. 1080.

On the Detection and Estimation of Zirconium in Tantalates and Niobates, see Rammelsberg (*Chem. Soc. J.* [2], x. 195).

Zirconium Bromide, ZrBr⁴, may be prepared by mixing zirconia with excess of pure sugar-charcoal, forming the mixture into balls with starch-paste, drying them, and heating them to bright redness in a current of carbon dioxide and bromine-vapour. It is a white powder, which appears crystalline under the microscope, volatilises easily at the heat of a gas-burner, and is not reduced to a lower bromide by ignition in a stream of hydrogen. In contact with water (or moist air) it is converted into the oxybromide, ZrBr³O, which separates from aqueous solution in fine transparent, needle-shaped crystals (Melliss, *Zeitschr. f. Chem.* [2], vi. 196).

Zirconium Chloride, ZrCl⁴, is formed by the action of silicium chloride in the form of vapour on zirconia (Troost & Hautesfeuille, *Compt. rend.* lxxv. 1819).

The oxychloride, ZrOCl², obtained by Hermann (v. 1080), crystallises, according to Melliss, not with 9H²O, but with 4½H²O.

Compounds of Zirconium with Aluminium and Silicon. 1. When 1 pt. of pulverised zircon is heated to whiteness with 5 pts. of cryolite powder, 1 pt. of aluminium, and 10 pts. of a mixture of the chlorides of potassium and sodium, an aluminium regulus is obtained, which, when treated with dilute hydrochloric acid, yields, together with finely-divided crystalline and darker-coloured silicon, laminar and proportionally large crystals, which may be separated from the silicon by elutriation. These crystals have the composition ZrAl³, or, if the silicon (6.72 p.c.) found in their hydrochloric acid solution be regarded as a third constituent, they may be represented by the formula Zr²Al³Si.

When zircon is fused with sodium carbonate, and the fused mass is exhausted with hot water, a residuum is obtained consisting of the compound 8ZrO².SiO².Na²O + 11H²O. Potassium carbonate yields in like manner the compound ZrO².K²O.2SiO², or ZrSiO⁴.K²SiO² (Melliss, *Zeitschr. f. Chem.* [2], vi. 296).

ZIRLITE. A hydrate of alumina from Zirl in the Tyrol (Pichler, *Jahrb. f. Min.* 1871, 67).

END OF THE SECOND SUPPLEMENT.
